Thus, vertical plane symptoms indicate bilateral *disturbances and the* symptoms appear symmetrically in the eyes, trunk or extremities Vertical plane symptoms appear in the sagittal plane, or the plane of the vertical semicircular canals On the other hand, horizontal plane symptoms appear in the horizontal plane, or the plane of the horizontal semicircular canals.

DANKWORT

Zum Schluss möchten wir hier Herrn Prof Dr Dr h.c. *Shunshiro Kondo* unsere herzliche Dankbarkeit dafür bezeigen, daß er uns freundlich beraten und diese Abhandlung durchsehen hat.

rapidly over a one to two day period regardless of the presence or absence of dizziness.

The positional and positioning tests with ENG recording were performed as follows (Uemura, 1969). After examination of spontaneous nystagmus in the supine position, a patient was asked to roll his entire body over slowly first to the right side and then back to the supine position. The lateral position was maintained for one minute. Next he turned to the left lateral position in the same manner and then back to the supine position. Observation of nystagmus was made under Frenzel glasses and ENG recording was simultaneously conducted. The test was repeated with the eyes open in the dark and with the eyes closed. The positioning test was performed by seating the patient, having him lie down rapidly with his head hanging backward for 30 seconds, and then return to the sitting position. The test was observed under Frenzel glasses and was repeated with the eyes open in the dark.

Patients were retested as often as possible until disappearance of nystagmus. The average time of testing was 4.8 with the average interval of 7.2 days.

Positional nystagmus (PN) and positioning nystagmus (PGN) were differentiated from spontaneous nystagmus (SPN), which continued to be present with an almost similar intensity in the positional and positioning tests, and were further divided into the following subgroups.

1. *Direction-fixed PN*

A nystagmus first occurs or increases in intensity with a change in position. It persists for over 30 seconds as long as the new position is maintained. When the supine position is resumed, nystagmus disappears or decreases to its original intensity.

2. *Direction-changing PN*

When assuming the left or right lateral position a nystagmus, whose direction is opposite to that present in the supine or the other lateral position, persistently occurs. This PN is further subdivided into geotropic (divergent) or apogeotropic (convergent) type, depending on whether the quick phases are to the ground or away from the ground.

3. *Horizontal PGN*

A transitory nystagmus which is mainly horizontal may occur when the position is changed from the supine to the right or left lateral position, or when changed from the sitting to the head-hanging position. It usually reaches a peak in several seconds and gradually recedes or disappears.

4. *Vertical PGN*

A transitory vertical nystagmus may be induced by the positioning test. Its character is similar to those described above or it has peak strength immediately after the head-hanging position is assumed.

RESULTS

1. *Findings in the initial tests*

The interval between the date of the onset of vertiginous attack and the time of initial testing ranged from 1 to 25 days, the average being 6.1 days. All of the 31 cases had nystagmus at the initial testing.

Table I shows the incidence of various types of SPN and PN (or PGN). The direction of a nystagmus present in the supine position was toward the involved ear in 17 cases and toward the opposite ear in 10 cases. In the remaining 4 cases no nystagmus was present in the supine

TRANSITION OF NYSTAGMUS TYPES IN UNILATERAL LABYRINTHINE DISEASES

Takuya Uemura, Naohiro Yamaguchi and Emiko Iwashima

From the Department of Otolaryngology, Tokyo Women's Medical College Tokyo Japan

Abstract In order to clarify changes in spontaneous and positional nystagmus which occurred during the course of peripheral labyrinthine diseases, 31 patients with Ménière's disease (17 cases), aural vertigo of unknown etiology (9 cases), and sudden deafness (5 cases) were tested repeatedly using ENG. The testing of each case was made 4.8 times on the average with an average interval of 7.2 days. Twenty-four cases (77.4 %) showed more than two of the following four types which are listed in serial order of occurrence: spontaneous (or direction-fixed positional) nystagmus toward the involved ear; geotropic direction-changing positional nystagmus, spontaneous (or direction-fixed positional) nystagmus toward the opposite ear; and apogeotropic direction-changing positional nystagmus. Thus, the above-mentioned order may be regarded as the uniform pattern in the nystagmus transition caused by acute unilateral labyrinthine diseases.

Positional and positioning tests have been recognized as essential for the diagnosis of vertigo and dizziness and are widely used as part of the routine examination of equilibrium function. However diagnostic determination of the location of lesions on the basis of positional and positioning nystagmus has not yet been established despite the existence of extensive literature on animal experiments and clinical observations. One of the reasons for this obscurity seems to be that changes in the features of positional nystagmus during the course of a disease have been disregarded.

The purpose of the present report is to describe the transition in the types of nystagmus following acute unilateral labyrinthine diseases and to disclose the regularity of these patterns.

MATERIALS AND METHODS

The positional and positioning tests using electronystagmographic (ENG) recording were performed on 189 patients twice or more durin[g] the course of disease for the seven year perio[d] from May 1963 to April, 1970 at the Depart[ment] of Otolaryngology Tokyo Women's Medical College. There were 45 patients who demonstrated the transition of nystagmus direction, after those with suspect of central vestibular lesions were excluded. For the purpose of this study 31 cases were selected on the basis of the following criteria: they had a clear time interval between the data of the onset of vertiginous attack and the time of examination, and the involved ear was determinable by means of the caloric or audiometric tests.

The 31 cases consisted of 15 males and 16 females, ranging in age from 19 to 60 with an average of 36. They included 17 cases of Ménière's disease, 9 cases of aural vertigo of unknown etiology and five cases of sudden deafness. Ménière's disease was defined as a disorder with repeated vertiginous attacks accompanied by auditory symptoms. Absence of otitis media, head trauma or arteriosclerosis and of any cranial nerve sign other than that of the eighth cranial nerve was a prerequisite for the diagnosis of Ménière's disease. A patient was diagnosed as aural vertigo of unknown etiology when he complained of clear vertigo and the presence of peripheral labyrinthine lesion was demonstrated by a significant reduction of caloric response or by audiometric findings but no evidence of neighboring brainstem involvement was concluded on the basis of neurological examination. A patient was diagnosed as sudden deafness when he complained of severe or complete hearing loss occurring instantly or progressing

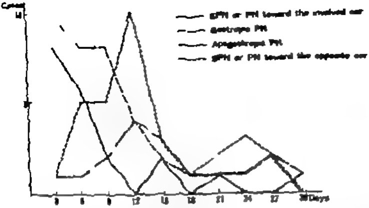

Fig. 2. Incidence of the four types of nystagmus after vertiginous attack.

two weeks. In the case of SPN (or PN) toward the opposite ear the incidence gradually increased, reached a peak on the 9–12th day and receded thereafter. No specific pattern in the incidence of apogeotropic PN was found because of the small number of cases.

5. *Transition of nystagmus types in individual cases*

Based on the above described results the types of SPN and PN appear to be divided into two one which occurs in early stages of the disease and the other which develops in later stages. Further details of transition of nystagmus types were examined on each of the 31 cases (Table III).

Of the 31 cases 18 (58.1 %) showed all three or a combination of any two of the following in the order described in Table III*a*: SPN (or PN) toward the involved ear, geotropic PN and SPN (or PN) toward the opposite ear (Fig. 3). Four cases (12.9 %) showed a combination of

position The incidence of a nystagmus toward the involved ear in the supine position was higher in the cases with SPN or direction-fixed PN than in those with direction-changing PN 12 of 17 for the former group and 5 of 10 for the latter

2. *Findings in the total 140 tests*

Table II lists the types of nystagmus in the total of 140 tests performed on the 31 cases. The different types of nystagmus were encountered in the following order of slightly decreasing incidence geotropic (direction-changing) PN was found in 40 (28.5) of the total of 140 tests SPN or (direction-fixed) PN toward the opposite ear 36 (25 7) apogeotropic (direction-changing) PN 25 (17 9 %) and SPN or (direction fixed) PN toward the involved ear 21 (15 0 %) No nystagmus was observed in 17 tests (12.1 %) There was an unclassifiable type of direction changing PN whose direction was the same in both lateral positions.

The tests were divided into two groups according to the time of testing (Table II and Fig. 1) There were 49 tests which were performed within the first week after a vertiginous attack and 91 tests were conducted in the second week or later Fewer cases of SPN (or PN) toward the involved ear were observed in the second group

Table II Types and time of occurrence of SPN and PN

	No. of cases	During the 1st week	During the 2nd week or later
SPN or PN toward the involved ear	21	15	6
Geotropic PN	40	1	19
Apogeotropic PN	25	2	23
SPN or PN toward the opposite ear	36	9	27
Nystagmus absent	17	1	16
Unclassifiable	1	1	0

than in the first group In contrast the majority of apogeotropic PN and SPN (or PN) toward the opposite ear was found in the second group. Although cases of geotropic PN were distributed equally in both groups, a type of geotropic PN which has a nystagmus toward the involved ear in the supine position was present only in the first group (Fig. 1b)

The incidence of the above-mentioned four types of nystagmus during the 30 day period after a vertiginous attack is shown in Fig. 2. In the case of SPN (or PN) toward the involved ear as well as of geotropic PN the incidence was the highest immediately after the day of onset and decreased abruptly during the subsequent

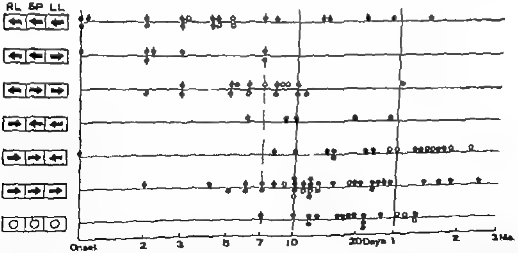

Fig 1 Findings in the total of 140 tests. The right ear was assumed to be involved in all the cases. Filled circles *indicate* cases with Ménière's disease or aural ertigo of unknown etiology while unfilled circles indicate cases with sudden deafness. The results of the *initial testing* are shown by the circles with vertical lines. *SP* supine position *RL* and *LL*, right and left side down positions.

No difference was present in the pattern of nystagmus transition between the patients with *Ménière's disease* or aural vertigo of unknown etiology both of which are thought to be caused similarly by autonomic dysfunction (Uemura et al., 1972), and those with sudden deafness.

COMMENTS

Changes in the features of nystagmus during the course of peripheral labyrinthine diseases especially of PN have scarcely been investigated. Gerlings (1948) described the transfer between direction-changing PN and SPN or direction-fixed PN of the patients who had otitis media or underwent ear surgery. Aschan & Stahle (1957) reported that direction-changing PN was found in 5 of the 21 cases with Ménière's disease tested during or after the attacks. In this series the transfer between direction-changing and direction-fixed PN was noted in 3 cases.

Although these findings had indicated that peripheral lesions might also cause direction-changing PN they did not clarify the relationship between the nystagmus pattern and the inner ear pathology.

The present study of the 31 cases, approximately two thirds of which started to receive follow-up examination within the first week following a vertiginous attack, demonstrated that SPN and PN could be divided into two types according to the time of occurrence: first, SPN (or PN) toward the involved ear and geotropic PN with the highest incidence immediately after the vertiginous attack; and second, SPN (or PN) toward the opposite ear and, presumably apogeotropic PN which had the peak of incidence approximately two weeks later. Furthermore, it appeared from the analysis of the test results of individual cases that SPN (or PN) toward the involved ear which is referred to as irritative nystagmus was followed by geotropic PN and SPN (or PN) toward the opposite ear referred to as paralytic or destructive nystagmus, by apogeotropic nystagmus.

Thus, the non-inflammatory inner ear diseases including Ménière's disease, aural vertigo of unknown etiology and sudden deafness were shown to have a uniform pattern in the appearance of nystagmus.

This suggests that these diseases may follow the similar course from the irritative to the paralytic process in the vestibular labyrinth. The transition from SPN (or PN) toward the opposite ear to apogeotropic PN was thought to be related to the recovery or compensatory process, because it occurred in the latest stage of the course.

MENIERE S DISEASE AND DIPHENIDOL

A Critical Analysis of Symptoms and Equilibrium Function Tests

T Futaki M Kitahara and M Morimoto

From the Department of Otolaryngology School of Medicine
Kyoto University Shogoin, Sakyo-ku Kyoto 606 Japan

Abstract In 24 patients with Ménière s disease, chemotherapy using Diphenidol (1 1 -diphenyl-4-piperidino-l-butanol hydrochloride), a non-phenothiazinic antiemetic agent, was carried out using the double-blind technique in the cross-over design. The prevalence and intensity of symptoms at the three stages were recorded every three weeks according to fixed scales which were graded vertigo, unsteadiness, tinnitus, nausea, headache, and shoulder stiffness. The hearing was measured by tone audiometry Equilibrium function tests were also performed every three weeks and these included the electronystagmographical procedure to determine caloric response and the ARG Tilt tests. Both symptoms and the results of equilibrium function tests, showed a higher incidence of improvement during the period of Diphenidol administration than during that of placebo. The difference was statistically significant with respect to vertigo, dizziness or unsteadiness, and general condition subjectively as well as caloric response and ARG Tilt tests. The Diphenidol effect consisted of an improvement of imbalance, both in the peripheral and in the central vestibular system through its neural and circulatory action. Only 8 of the patients dropped out and no side effects were observed in this series. Both the feasibility of the graded symptom scales and the utility of each parameter obtained from the equilibrium function tests are discussed in connection with testing of the drug in various stages of the disease.

Ménière s disease is presently diagnosed by clinical symptoms such as episodic vertigo tinnitus and loss of hearing. In addition to the characteristic clinical features, the disease has attracted considerable interest because of its usually recurrent or chronic nature The unpleasant and partly incapacitating nature of the symptoms has been a strong incentive in the search for suitable forms of therapy Not all patients with Ménière s disease necessarily require surgery Rather this treatment should be restricted to those who complain of incapacitating, frequent longlasting, severe attacks of vertigo Conservative treatment should be adequate for patients with mild cases of Ménière s.

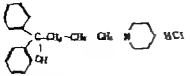
Chemotherapy for Ménière s includes vasodilators, histaminics, psychotropics, vestibular suppressives, salt and water restriction, diuretics and steroids

A most judicious prescription of diuretics and steroids is necessary as side effects such as decreased potassium levels in the serum, ulceration in the alimentary canal and the moon face are often observed Diuretic and steroid chemotherapy is therefore not suitable for long term administration but should be prescribed for cases of exacerbation of labyrinthine disorders in chronic cases.

Certain vasodilators and histaminics have been prescribed and reported as effective in the preventive treatment of Ménière s. Vestibular suppressives also may be employed during the irritative stage of Ménière s

To eliminate stress factors which often enhance the symptoms, sedatives or tranquillizers may also be employed Despite these various prescriptions, no specific agent which is both safe and effective has been formulated Taking the following factors into consideration diphenidol was proposed for the treatment of Ménière s disease for the following reasons

(1) Diphenidol is an antiemetic agent with a non phenothiazinic chemical structure It was



1, 1,-diphenyl-4-piperidine-1-butanol hydrochloride

Fig. 1. Chemical structure of diphenidol.

synthesized by Leonard *et* al. in 1966 (Fig. 1). It can block apomorphine-induced emesis as rapidly as chlorpromazine and has minimal depressant action on the C.N.S.

(2) Electrophysiologically the excessive discharge at the vestibular nuclei was depressed by the i.v. administration of diphenidol to cats (Matsuoka, 1972).

(3) This agent successfully diminishes experimentally induced nystagmus (Matsunaga, 1972).

(4) The velocity of blood flow in the vertebral artery is selectively and significantly increased on the side of the affected labyrinth (Shiraishi, 1971).

(5) This agent has been reported to be effective for patients with vertigo (Smoot, 1965; Rowan, 1968; Matsunaga et al., 1972) and motion sickness (Berry & McConnell, 1965).

(6) From the results of studies as well as clinical experience there appears to be a considerable margin between the therapeutic dose and that which produces undesirable side effects.

Encouraged by these favourable properties of diphenidol, a controlled clinical trial was carried out on 24 patients with typical and atypical Ménière's disease. One of the main objectives was to investigate whether or not the efficacy of the drug as the result of parenteral administration could be elicited over a period of 3 weeks of oral administration and, in addition, to determine the relationship between changes in subjective symptoms and objective findings such as

Table I. *Grading of symptoms in Ménière's disease according to criteria set for the present study*

Tinnitus	Vertigo	Dizziness and unsteadiness	Nausea
0 None	None	None	None
0.5 Slight, periodic			
1.0 Slight, continuous or moderate, periodic	Seldom or frequent, intermediately transient rotatory vertigo or severe but brief (< 30 min), max. 2/mo.	Unreliable function in situations requiring balance. Rapidly transient, slight rotatory vertigo on quick head movements	Accompanied by dizziness
1.5 Continuous, fluctuating from slight to moderate			
2.0 Continuous, moderate or fluctuating from slight to severe. Intermittent, severe	Intense but brief attacks, > 2/mo. Intense, lengthy (> 30 min) often with vomiting, max. 2/mo.	Short periods (< 30 % prevalence) of balance disturbance	Occasionally accompanied by dizziness
2.5 Continuous, fluctuating from moderate to severe			Continuously present
3.0 Continuous, severe	Intense, lengthy >/mo.	Longer periods (> 30 prevalence) of balance disturbance	

Audible only in quiet environment.
Audible in ordinarily noisy environment but diversible, i.e., not observed when attention focused on work, etc.
Constantly noticed in all ordinary acoustic environments and even when concentrating on work, etc.

equilibrium function tests. Assessement of the drug for side effects and a determination of the reliability of the test was also considered, as the cross-over method involved necessitated a trial of 6 weeks.

METHODS

The following distinctions, criteria and procedure were applied during the entire series.

At the start of the trial, patients who subjectively had a complete triad of symptoms including idiopathic vertigo tinnitus and hearing loss of the perceptive type were diagnosed as typical Ménière s disease and those with episodic vertigo without or at least unaware of cochlear signs were regarded as atypical Ménière s.

Since initial symptoms of Ménière s disease are so varied and since many months may pass before the syndrome is complete in the former the diagnosis is more uncertain in the latter in

Headache	Stiffness in the shoulders

which the initial symptoms are vestibular onl Patients both with labyrinthine disease of know etiology and with extralabyrinthine lesions whi could cause the attacks, were carefully elimi ated from the Ménière s disease grouping. Th 24 patients with Ménière s were selected for controlled clinical evaluation of diphenidol. Th symptoms of Ménière s disease were graded an recorded according to the scales described i Table I with reference to the report by Kloe hoff & Lindblom in 1967 covering hydrochloro thiazide The scales consisted of a numeric grading of the symptoms, with respect to inter sity and prevalence The evaluation was mad three times i e at the beginning of trial, weeks after the first medication and a further weeks after the second medication, on the bas of verbal statements by the patients themselve A particular doctor was assigned to each patien in order that variation by multiple inquirer should not occur

The design for the trial was a cross-ove method (Fig. 2) lasting for 6 weeks. One bottl of tablets was allotted to each patient. Content were either diphenidol or placebo of identica appearance (lactose) and each bottle was labelle with its own code number randomised by th controller The patients were instructed t take 1 tablet three times a day after meals, an each bottle was carefully checked 3 weeks later One active tablet contained 25 mg of diphenidol, i e 75 mg a day The code was not broken unti the study was completed These periods wer preceded by a week of washing-out medication. No other chemical agent was ingested throughout the trial.

Side effects were carefully checked at each end point of medication.

Audiometry Pure tone audiometry was performed three times, using the Rion-AA 34 The meaning of the hearing-loss figures, i.e $a+2b+c/4$ at the frequencies 500 (a) 1 000 (b) and 2 000 (c) Hz was taken as representative of each audiogram

Equilibrium function tests Equilibrium function tests were also performed every 3 weeks and these included the electronystagmographical

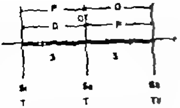

Fig. 2. Design of a 6-week trial using the cross-over technique. *P*, Placebo; *D*, diphenidol; *S*, symptom; *T*, tests of equilibrium function.

procedures as follows: (1) ARG-Tilt test and (2) the caloric test.

Recording no. 1 was carried out simultaneously with ENG, using a strain-gauge-type amplifier (Kyowa Denki Ltd.) conducted from the accelero-meter attached to the forehead that was set at a speed of 1 /sec by electric motor driven goniometer (manufactured by Matsui). Recording no. 2 was carried out by three channelled d.c. ENG (San-ei Sokki Ltd.).

The caloric tests were carried out with the patient in a supine position and using 50 cc of water at 30°C. Ice-cold water was used in cases where no reaction was obtained with this stimulus. Immediately after the irrigation, the room was darkened.

Statistical analysis. Concerning subjective symptoms, the sequential analysis (Armitage) was employed for both global comparative judgement and for each symptom. As to the objective findings, i.e. the pure tone audiometry and the equilibrium function tests, these were analysed using T tests. In addition, some were illustrated in the diagram of the sequential analysis.

RESULTS

1. *Symptoms*

An example of the accommodated value of each subjective symptom based on the judgement criteria is shown in Table II (with the 2nd sequence patient of Code number 73). Since the sum of $(S_1\text{-}S_2)$ of each symptom was larger than that of $(S_1\text{-}S_3)$, the second bottle of the drug was estimated effective or as the real drug and (+) was written. In the bottom row placebo (*P*) and diphenidol (*D*) were the order of the administration shown by the controller after breaking the seal for blindness with code number 73 at the completion of the entire series of patients. This global comparative judgement is an example of "win" since the order of (−) and (+) were in accord with that of *P* and *D* respectively.

The judging of the 24 patients according to symptoms is shown in Table III. When the results in Table III were graphically analysed by the sequential technique of Armitage, the curve crossed the limit line at the sixth case (Fig. 3). It was therefore concluded that diphenidol was significantly more effective in the global comparative judgement of subjective symptoms than was placebo ($\alpha=0.05$, $1-\beta=0.95$ and $\theta=0.85$).

With regard to each symptom the sequential analysis was also carried out. Fig. 4 shows the results related to each symptom. It was also concluded that diphenidol was more significantly effective than placebo in vertigo (*V*) and dizziness (*D*) or unsteadiness ($\alpha=0.05$, $1-\beta=0.95$ and $\theta=0.85$). The others remained in the lattice, i.e. more cases should be examined.

2. *Pure tone audiometry and equilibrium function tests*

Yielded values with diphenidol and placebo concerning the parameter Objective Findings are shown in Table IV.

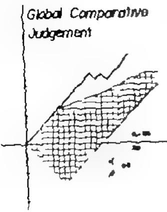

Fig. 3. Sequential analysis of global comparative judgement. *N*: Sequential number reaching significant level. (α 0.05, $1-\beta$ 0.95, θ = 0.85).

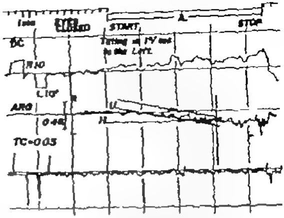

Fig. 5. A recording of ARG-Tilt test. *A*, Angle of falling on tilting; *H*, head inclination; *U*: degree of unrest head swaying.

crease in *A* and a decrease in *H* and *U* can be interpreted as an improvement in the labyrinthine righting reflex (Kitahara, 1965). The results after administration of diphenidol showed a significant decrease in both head inclination and unrest head swaying at the 0.05 level, but an increase in the angles of falling was not significant, as seen in Table IV.

Total judgment of ARG-Tilt test, providing a "win" was recorded in a case with more than two parameters of *A*, *H* and *U* effective with diphenidol, was shown in sequential analysis (Fig. 6). This curve crossed the limit line at the ninth case. Thus the results were significant (α = 0.05, $1-\beta$ = 0.95, θ = 0.85). Accordingly it was concluded that diphenidol, rather than the placebo, caused significant improvement in the labyrinthine righting reflex for the maintenance of body equilibrium.

Caloric responses. As parameters of caloric nystagmus the following were used: (1) a ratio of differences between the right and left in maximum velocity of the slow component: $(R-L)/(R+L)$ (Mv); (2) a ratio of differences between the right and left in maximum intensity (Stahle, 1958): $(R-L)/(R+L)$ (MI); and (3) sum of the right and left maximum frequency of nystagmus for 10 sec. As for the maximum velocity (Mv), *t*-test showed that diphenidol caused a decrease in the right-left differences of caloric response at the 0.05 level.

gradation of symptoms was thus employed d the antivertiginous effect of diphenidol oved to be more dominant than the antiemetic e, as well as the suppressive effect in cochlear mptoms such as tinnitus. This dominance ight be responsible for the improvement in the neral condition of the symptom complex.

Although the mechanism and site of action of iphenidol may to some degree have been ucidated, the indices of choice in objective indings should be given careful consideration. Pure tone audiometry and equilibrium function tests including electronystagmographical procedures were chosen because these are the well established methods in investigation of Ménière's disease. Regarding objective findings, there is no mention of the efficacy of diphenidol in the literature, except for Shiraishi's report concerning the blood flow in the vertebral artery as quoted earlier. Matsunaga reported that a discrepancy exists between the symptomatic efficacy and the results of audiometry and equilibrium function tests including investigation of spontaneous and positional nystagmus with Frenzel's glass, stepping tests and vertical writing tests. Electronystagmographical procedures employed in this study are considered to result in a higher detectability rate than with the above mentioned screening tests. The audiometric results in the present study parallel those of Smoot & Matsunaga in that no change was detected in pure tone audiometry. It has been reported that hearing improvement in the affected labyrinth in Ménière's disease is brought about by some diuretics, i.e. hydrochlorothiazide (Klockhoff & Lindblom, 1967) glycerol (Klockhoff & Lindblom, 1966) and furosemid (Futaki, Kitahara & Morimoto, 1975). These authors assumed that a hearing shift was caused by temporary reduction of endolymphatic hydrops as a result of systemic diuresis. Compared with the action of diuretics, that of diphenidol on the cochlea appears to be more indirect. In fact, as another cochlear symptom, tinnitus remained in the lattice (Fig. 4).

Regarding equilibrium function tests, two types of investigation were performed, mainly in connection with the two anatomical neural pathways, i.e. the vestibulo-spinal and the vestibulo-oculomotor tract, both including reticular connections. For investigating the natural reactions of the labyrinth which maintains the equilibrium of the body, the examination related to the labyrinthine righting reflex, i.e. ARG-Tilt test (Kitahara, 1965) was carried out. He reported that in more than 90% of 46 patients with Ménière's disease, the imperfect occurrence of the head righting reflex was revealed, and that in Ménière's disease the results of the tilt test were closely related to those of Hallpike's caloric test.

As for the results of ARG-Tilt test in this study, it was clearly demonstrated that diphenidol caused a significant improvement of the labyrinthine righting reflex required to maintain body equilibrium. As quoted above, the improvement shown by the results of ARG-Tilt tests was also closely related to the results obtained in caloric responses which revealed a significant reduction of imbalance of labyrinthine function during the period of diphenidol administration.

The caloric test has been recognized as one of the most reliable tests in determining which ear is impaired in various vestibular examinations (Cawthorne et al., 1942, Stahle & Bergmann, 1967). Therefore, the improvement in caloric response is considered as essential for treatment of Ménière's disease. Since the chief aim of therapy is to produce a homeostatic state, either medically or surgically, it is desirable that the pharmacokinetics of a drug should act selectively with a balanced state as a result.

Both the damping of the excessive discharge at the vestibular nuclei in cats (Matsuoka, 1972) and the selective increase in blood flow in the vertebral artery on the side of the affected labyrinth in man (Shiraishi et al., 1971) on injecting with diphenidol, may be regarded as being related to the causal mechanism of the improved objective findings after oral administration of diphenidol for 3 weeks (75 mg a day).

Finally, it is also emphasized that side effects were nil and that only 2 (8%) patients "dropped out".

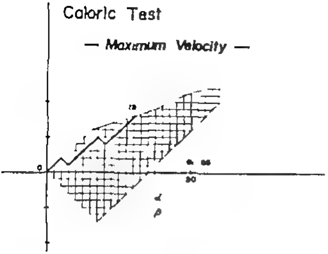

Fig 7 Sequential analysis of caloric tests in maximum velocity

is shown in Fig. 7 The curve crossed the limit line at the twelfth case which indicates that this drug significantly reduces the imbalance of the labyrinthine functions ($\alpha=0.05$ $1-\beta=0.95$ $\theta=0.85$)

As for the maximum intensity the t test showed at the 0.05 level that diphenidol significantly decreases the right-left differences, in comparison with placebo as was also seen with sequential analysis at $n=12$ ($\alpha=0.05$ $1-\beta=0.95$ $\theta=0.85$) (Fig. 8)

As for the maximum frequency of nystagmus for 10 sec, neither t test nor sequential analysis showed any significant result. As this drug significantly decreased the imbalance of excitability of the labyrinth, states close to that of equilibrium were realized.

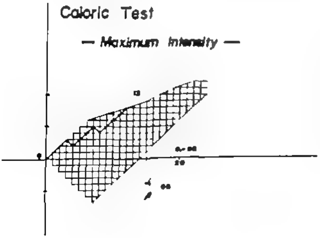

Fig 8 Sequential analysis of caloric tests in maximum intensity

DISCUSSION

In this controlled study both the symptoms and the results of equilibrium function tests showed a higher incidence of improvement during the period of diphenidol administration than during that of placebo The difference was statistically significant with respect to vertigo dizziness or unsteadiness and general condition subjectively as well as caloric response and ARG-Tilt test.

Smoot reported in 1965 from his open trial with oral administration of diphenidol that the drug was safe and effective in 8 patients with non-operative labyrinthine disturbances, including 6 Ménière s patients and in 14 patients with post-operative labyrinthine disorders chiefly caused by stapedectomy There is a distinct difference between unavoidable postoperative vertigo and episodic vertigo of Ménière s disease regarding occurrence and duration. Also since the vertigo of labyrinthitis and sudden deafness is more clear cut than that of Ménière s disease, the design of the clinical trials should be carefully determined, as the disease is usually recurrent and of a chronic nature Such being the case, the cross-over method to detect intra individual differences was chosen for this study

The symptomatic results of the present study are in agreement with two controlled studies by Rowan (1968) and Matsunaga et al. (1972). These two reports included vertiginous patients with various etiologies, such as central vertigo as a result of arteriosclerosis, and traumatic vertigo Due to insufficient stratification it was only estimated that diphenidol appeared to be more effective in peripheral than in central vertigo and firm conclusions about the drug s relative efficacy were not drawn.

The characteristic clinical features of Ménière s disease are not only related to the varied presence of the triad but also to the existence of accompanying symptoms such as nausea headache and shoulder stiffness. In order to estimate the efficacy of the drug in this disease it is important that two aspects must be considered, the variation in each symptom and the general condition of the symptom complex. The numeri-

cal gradation of symptoms was thus employed and the antivertiginous effect of diphenidol proved to be more dominant than the antiemetic one, as well as the suppressive effect in cochlear symptoms such as tinnitus. This dominance might be responsible for the improvement in the general condition of the symptom complex.

Although the mechanism and site of action of diphenidol may to some degree have been elucidated, the indices of choice in objective findings should be given careful consideration. Pure tone audiometry and equilibrium function tests including electronystagmographical procedures were chosen because these are the well established methods in investigation of Ménière's disease. Regarding objective findings, there is no mention of the efficacy of diphenidol in the literature, except for Shiraishi's report concerning the blood flow in the vertebral artery as quoted earlier. Matsunaga reported that a discrepancy exists between the symptomatic efficacy and the results of audiometry and equilibrium function tests including investigation of spontaneous and positional nystagmus with Frenzel's glass, stepping tests and vertical writing tests. Electronystagmographical procedures employed in this study are considered to result in a higher detectability rate than with the above-mentioned screening tests. The audiometric results in the present study parallel those of Smoot & Matsunaga in that no change was detected in pure tone audiometry. It has been reported that hearing improvement in the affected labyrinth in Ménière's disease is brought about by some diuretics, i.e. hydrochlorothiazide (Klockhoff & Lindblom, 1967) glycerol (Klockhoff & Lindblom, 1966) and furosemid (Futaki, Kitahara & Morimoto 1975). These authors assumed that a hearing shift was caused by temporary reduction of endolymphatic hydrops as a result of systemic diuresis. Compared with the action of diuretics, that of diphenidol on the cochlea appears to be more indirect. In fact, another cochlear symptom, tinnitus remained in the lattice (Fig. 4).

Regarding equilibrium function tests, two types of investigation were performed, mainly in connection with the two anatomical neural pathways, i.e. the vestibulo-spinal and the vestibulo-oculomotor tract, both including reticular connections. For investigating the natural reactions of the labyrinth which maintains the equilibrium of the body the examination related to the labyrinthine righting reflex, i.e. ARG Tilt test (Kitahara, 1965) was carried out. He reported that in more than 90% of 46 patients with Ménière's disease, the imperfect occurrence of the head righting reflex was revealed, and that in Ménière's disease the results of the tilt test were closely related to those of Hallpike's caloric test.

As for the results of ARG-Tilt test in this study it was clearly demonstrated that diphenidol caused a significant improvement of the labyrinthine righting reflex required to maintain body equilibrium. As quoted above, the improvement shown by the results of ARG-Tilt tests was also closely related to the results obtained in caloric responses which revealed a significant reduction of imbalance of labyrinthine function during the period of diphenidol administration.

The caloric test has been recognized as one of the most reliable tests in determining which ear is impaired in various vestibular examinations (Cawthorne et al., 1942 Stahle & Bergmann, 1967). Therefore, the improvement in caloric response is considered as essential for treatment of Ménière's disease. Since the chief aim of therapy is to produce a homeostatic state, either medically or surgically it is desirable that the pharmacokinetics of a drug should act selectively with a balanced state as a result.

Both the damping of the excessive discharge at the vestibular nuclei in cats (Matsuoka, 1972) and the selective increase in blood flow in the vertebral artery on the side of the affected labyrinth in man (Shiraishi et al., 1971) on injecting with diphenidol, may be regarded as being related to the causal mechanism of the improved objective findings after oral administration of diphenidol for 3 weeks (75 mg a day).

Finally it is also emphasised that side effects were nil and that only 2 (8 %) patients "dropped out"

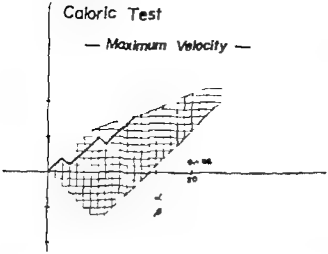

Fig 7 Sequential analysis of caloric tests in maximum velocity

is shown in Fig. 7 The curve crossed the limit line at the twelfth case which indicates that this drug significantly reduces the imbalance of the labyrinthine functions ($\alpha = 0.05$ $1-\beta = 0.95$ $\theta = 0.85$)

As for the maximum intensity the *t* test showed at the 0.05 level that diphenidol significantly decreases the right-left differences, in comparison with placebo as was also seen with sequential analysis at $n = 12$ ($\alpha = 0.05$ $1-\beta = 0.95$ $\theta = 0.85$) (Fig. 8)

As for the maximum frequency of nystagmus for 10 sec, neither *t* test nor sequential analysis showed any significant result. As this drug significantly decreased the imbalance of excitability of the labyrinth, states close to that of equilibrium were realized

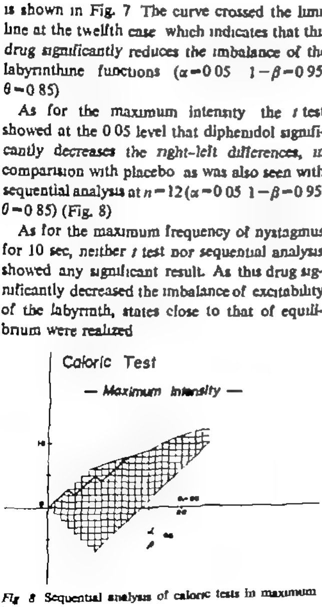

Fig 8 Sequential analysis of caloric tests in maximum intensity

DISCUSSION

In this controlled study both the symptoms and the results of equilibrium function tests showed a higher incidence of improvement during the period of diphenidol administration than during that of placebo The difference was statistically significant with respect to vertigo dizziness or unsteadiness and general condition subjectively as well as caloric response and ARG-Tilt test.

Regarding equilibrium function tests, two types of investigation were performed, mainly in connection with the two anatomical neural pathways, i.e. the vestibulo-spinal and the vestibulo-oculomotor tract, both including reticular connections. For investigating the natural reactions of the labyrinth which maintains the equilibrium of the body, the examination related to the labyrinthine righting reflex, i.e. ARG-Tilt test (Kitahara, 1965) was carried out. He reported that in more than 90% of 46 patients with Ménière's disease, the imperfect occurrence of the head righting reflex was revealed, and that in Ménière's disease the results of the tilt test were closely related to those of Hallpike's caloric test.

As for the results of ARG-Tilt test in this study, it was clearly demonstrated that diphenidol caused a significant improvement of the labyrinthine righting reflex required to maintain body equilibrium. As quoted above, the improvement shown by the results of ARG-Tilt tests was also closely related to the results obtained in caloric responses which revealed a significant reduction of imbalance of labyrinthine function during the period of diphenidol administration.

The caloric test has been recognized as one of the most reliable tests in determining which ear is impaired in various vestibular examinations (Cawthorne et al., 1942, Stahle & Bergmann, 1967). Therefore, the improvement in caloric response is considered as essential for treatment of Ménière's disease. Since the chief aim of therapy is to produce a homeostatic state, either medically or surgically, it is desirable that the pharmacokinetics of a drug should act selectively with a balanced state as a result.

Both the damping of the excessive discharge at the vestibular nuclei in cats (Matsuoka, 1972) and the selective increase in blood flow in the vertebral artery on the side of the affected labyrinth in man (Shiraishi et al., 1971) on injecting with diphenidol, may be regarded as being related to the causal mechanism of the improved objective findings after oral administration of diphenidol for 3 weeks (75 mg a day).

Finally, it is also emphasised that side effects were nil and that only 2 (8%) patients "dropped out".

SUMMARY

A double blind trial to evaluate a new agent, non phenothiazinic antiemetic-diphenidol, synthesized in 1966 was carried out on 24 patients with confirmed Ménière's disease. Clinical and statistical evaluation of the results showed that diphenidol is indeed effective for subjective symptoms and positive results were evident in equilibrium function tests. There were no apparent side effects. Difficulties related to conducting anti-vertiginous tests in chronic Ménière's are discussed.

ZUSAMMENFASSUNG

Ein Double Blind Versuch zur Abschätzung eines neuen Agens, nonphenothiazinischen Antiemetik Diphenidols, das 1966 synthesiert wurde, wurde an 24 Patienten mit chronischer Ménièrescher Krankheit durchgeführt.

Klinische und statistische Auswertung der Ergebnisse zeigt dass das Diphenidol deutlich auf die subjektiven Symptome einwirkt. Das positive Resultat ist durch den Gleichgewichtstest klar geworden.

Es gibt keine offensichtliche Nebenwirkungen. Schwierigkeiten des Gegenschwindel-Tests bei chronischer Ménièrescher Krankheit wurden diskutiert.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude to Professor S. Takaori Kyoto University Dept. of Pharmacology for acting as controller during this series, to Mr K. Hatsuyama of Nihon-Shinyaku Co Ltd. Kyoto for technical assistance, and to Miss M Ohara, Kyoto University for preparation of the manuscript.

LE TRAITEMENT DU « VERTIGE » POST TRAUMATIQUE ACCOMPAGNÉ D ATAXIE CÉRÉBELLEUSE FRUSTE

Efficacité de la procaïnisation des muscles érecteurs lombaires

Nobuya Ushio

Service d'oto-rhino-laryngologie Ecole de Médecine, Université de Tokushima, Japan et Centre Hospitalier Sainte-Anne Laboratoire de Stabilométrie

. est vérifié expérimentalement sur des animaux et des mannequins que le tissu et les éléments vasculaires, articulaires et osseux cervicaux subissent une lésion fonctionnelle ou organique lorsque l'axe du corps d'un sujet est soumis à une hyperextension ou une hyperflexion. Il est bien connu que parmi tous les tissus et les éléments anatomiques cervicaux le propriocepteur situé dans les tissus de soutien mous (les muscles), les organes de Ruffini dans les ligaments, la capsule et l'articulation, les organes de Golgi dans les tendons, les nerfs sympathiques, et l'artère vertébrale, peuvent être concernés lors de l'apparition du vertige cervical. Par conséquent on a fait depuis longtemps des recherches sur les rôles que jouent au moment de l'apparition du vertige » cervical l'anomalie fonctionnelle et la lésion organique de ces tissus et de ces organes. Il y a déjà plusieurs théories sur ce problème dont voici les principales (1) l'hyperfonctionnement du grand sympathique cervical, (2) le dysfonctionnement du reflexe cervical, (3) la circulation insuffisante de l'artère vertébrale.

Nous avons aussi indiqué que l'hypertonicité des tissus de soutien mous cervicaux, est une des causes principales de l'apparition du vertige cervical. Or en observant des cas de vertige » chez des traumatisés cervicaux, nous avons remarqué qu il y avait de nombreux cas accompagnés de douleurs lombaires et que ces dernières se rencontrent en proportion directe avec le vertige (Ushio 1970). Dans ces cas, la plupart s accompagnent en même temps d anomalies fonctionnelles tronculaires et cérébelleuses. Ceci nous a conduit à penser que les tissus de soutien mous lombaires, le tronc et le cervelet, avaient un rapport les uns avec les autres comme une détente et une cible, et se rattachaient à l'apparition du « vertige » cervical. Par conséquent, l'essentiel du traitement du ertige dans ces cas, consiste, comme nous l'avons indiqué dans le cas du vertige cervical, d une part à la correction de l'hypertonicité des tissus de soutien mous lombaires et d autre part au rétablissement de fonctionnement du système nerveux central tels que le tronc et le cervelet.

En tant que traitement pour rétablir le fonctionnement du tronc et pour faire disparaître le ertige, nous avons souvent signalé qu'il est efficace de donner des médicaments agissant sur le fonctionnement du tronc, c est à dire, par exemple la Centrophénoxine (Lucidril), CDP-choline (Nicholin) (Hinoki et al., 1967 Ushio et al., 1970). Mais jusqu ici, nous n avons pas encore perfectionné le traitement pour le contrôle efficace des symptômes cérébelleux frustes pour accélérer l'amélioration du vertige.

Dans un article antérieur , ai montré que dans les cas des traumatisés cervicaux accompagnés d'une part de troubles non définis comme des douleurs lombaires qui peuvent être considérées

9-7338 a

comme l hypertonicité des tissus de soutien mous lombaires et d autre part de symptômes cérébelleux, il y en a un certain nombre dans lesquels la fonction d équilibre est améliorée par la fixation des lombes avec un corset (l examen de la fonction d équilibre se normalise) et de plus le symptôme cérébelleux fruste disparait. L examen de la fonction cérébelleuse au niveau des membres supérieurs épreuve des index, de l index nez, des marionnettes se normalise.

J ai dit en présentant les cas examinés que chez ces patients le traitement pour améliorer l'hypertonicité des tissus de soutien mous lombaires peut faire disparaître le symptôme cérébelleux et par conséquent peut être aussi un traitement du « vertige » La procaïnisation dans la partie douloureuse des lombes, est un des traitements, comme je l ai remarqué, qui peut agir d une façon efficace (Ushio 1970 1971)

Dans cet article je voudrais expliquer des cas examinés de ce point de vue, et ajouter certaines remarques

EXAMENS CLINIQUES ET THERAPEUTIQUE

1 *Sujets examinés*

J ai pu observer 28 cas de « vertiges » traumatiques accompagnés de signes cérébelleux ataxiques frustes, dans lesquels le sujet se plaignait de douleurs (élancement) dans la région lombaire Sur ces 28 cas, il y a 4 cas chez lesquels j ai pu traiter de manière répétée le patient suivant la méthode présentée et expliquée ci-dessous et suivre l évolution pendant un temps relativement long.

2 *Procédé thérapeutique de procaïnisation des muscles érecteurs lombaires*

On procède à 2 reprises à une injection de 7 5 à 10,0 cc de solution à 1 % de procaïne (additionée de 2 mg de Rinderon steroïd) dans les muscles érecteurs lombaires du *côté douloureux* à la hauteur de L3 et L4 et à 3 ou 4 cm de profondeur de telle sorte que le volume total de la solution injectée soit de 15 à 20 cc.

3 *Tests utilisé et leurs critères*

A *Pour examiner la fonction d'équilibre J'ai choisi les tests suivants*

1 Tests des réflexes d orthostatisme il y en deux l'un est le test de Romberg et l'autre le test de Mann. Dans les deux tests j ai utilisé un accéléromètre placé sur la tête du sujet pour enregistrer les oscillations corporelles, de telle sorte que soient objectivés et mesurés ces résultats.

2. Test du nystagmus spontané et test du *nystagmus de position.*

3 Test du piétinement de Fukuda, au cours duquel on demande au sujet de faire 100 pas en piétinant sur place.

4 Test du nystagmus optocinétique, employant *un stimulateur optocinétique de type Jung* (modifié) qui projette à raison d une fois/sec., des raies verticales de lumière qui se déplacent, à la vitesse de 0 (vitesse minimale) à 180°/sec. (vitesse maximale) de droite à gauche ou de gauche à droite

En outre nous avons effectué sur tous les sujets à l occasion de la première visite d autres examens pour mieux connaitre la fonction d équilibre Epreuve calorique rotatoire, de pôrsuite et test d écriture

B *Pour examiner l'ataxie cérébelleuse fruste on utilise les test suivants*

1 Epreuve des index
2. Epreuve de l index nez
3 Epreuve des marionnettes
4 Epreuve du genou talon
5 Réflexe H examen de la courbe de fréquence du pourcentage de diminution faite d après la méthode proposée par Ioku (Ioku 1969)

Dans les tests épreuve des index épreuve de l index nez et épreuve des marionnettes, l évolution de l'état ataxique après le traitement sera suivie par *l augmentation ou la diminution du nombre d erreurs sur dix essais* et on considère comme significatif le changement de ce nombre de plus ou moins 3 Dans le test épreuve des martionnettes, ne sera considéré comme signifi-

catif que le changement visible dans l'habileté des mouvements de prosupination.

4. *Résultats du traitement*

Comme il est indiqué ci-dessus, j'ai procédé à l'injection de procaïne dans la partie douloureuse des lombes des 28 sujets souffrant de « vertiges » traumatiques accompagnés de signes d'ataxie cérébelleuse observés aux membres supérieurs et se plaignant de douleurs lombaires exclusivement, à prédominance unilatérale, pour observer objectivement leur évolution au moyen des tests signalés précédemment. Sur ces 28 cas, il y en a 19 où la procaïnisation s'est montrée efficace à la première injection mais dont l'évolution n'a pu être suffisamment suivie, il y en a aussi 5 où le traitement par la procaïnisation a été abandonné à la suite de la première injection dont l'effet n'était pas satisfaisant.

Sur les 4 cas qui restent, 3 ont permis le traitement par la procaïnisation lombaire pendant un temps assez long pour observer son effet d'une manière satisfaisante et l'autre cas m'a donné une occasion d'observer l'évolution d'un sujet traité d'abord par la procaïnisation et ensuite par la traction lombaire.

Voici maintenant la description détaillée de chaque cas.

Cas 1 H.N., ♀, 39 ans, traumatisme cervical. Le sujet a eu un accident de voiture, celle-ci a été heurtée à un croisement par derrière, à l'arrêt, et la patiente a reçu à la tête un choc dont elle ne s'est pas rendu compte malgré sa conscience restée intacte au moment de l'accident. Elle se plaint d'une sensation de « vertige ». Elle avait dès le lendemain de l'accident mal au cou et des nausées et environ dix jours après le choc sont apparus la sensation de « vertige » (ou de titubation), la douleur lombaire droite, et mal à tête et la sensation de tête lourde. L'ortopédiste et l'ophtalmologiste auprès de qui notre patiente avait consulté n'avaient pas relevé de symptômes de quelque importance.

A. Résultats des examens d'équilibre lors de la première visite

1. Examens des réflexes d'orthostatisme.

Test de Romberg oscillations avec les yeux ouverts et renversement vers l'arrière les yeux fermés.

Test de Mann tendance à tomber en arrière avec les yeux ouverts et fermés.

2. Test du nystagmus spontané et du nystagmus de position absence de nystagmus, présence de petits mouvements oculaires horizontaux, rapides et lents, observés la tête en position normale aussi bien qu'inclinée dans toutes les directions.

3. Test d'écriture de Fukuda 5 lettres sont tracées verticalement 3 fois de suite les yeux bandés, l'écriture est inclinée vers la droite de 9°, malgré cela aucun signe ataxique, comme par exemple le tremblement de la main, n'y était observé.

4. Test du piétinement de Fukuda notre patiente a montré une déviation dont voici les caractéristiques distance 140 cm, angle de déviation 45° et angle de rotation du corps 45°. Elle s'accompagnait de chancellement (Démarche de l'ours).

5. Test du nystagmus rotatoire de Bárány et test calorique le résultat obtenu dans ces tests ne donne pas de différence droite gauche dans l'excitabilité labyrinthique.

6. Test du nystagmus optocinétique le sujet a reçu les stimuli optocinétiques. La réaction du système oculaire de l'examinée à l'égard de ces derniers était normale, le nystagmus vers la droite aussi bien que vers la gauche se produisait vivement dès que les stimuli étaient donnés.

7. Test de poursuite d'un objet en mouvement les yeux, l'un aussi bien que l'autre, pouvaient poursuivre régulièrement l'objet en mouvement.

8. Examen de l'équilibre sous l'effet de l'andrénaline.

L'écriture de notre sujet, dix minutes après une injection sous-cutanée d'adrénaline (0,006 mg/kg), ne présentait pas d'inclinaison plus grande qu'avant l'injection, ni de trémolo (tremblement de main).

B. Examen de l'acuité auditive. Aucun symptôme d'hypoacousie ni du côté droit ni du côté gauche était remarqué.

C. Examens de l'équilibre et évolution des

Fig. 1 Test de Mann ( ) Avant traitement tendance à tomber en arrière avec les yeux ouverts et fermés. (*b*) 7 jours après la quatrième procaïnisation une légère oscillation latérale a été observée les yeux ouverts au lieu de la tendance à tomber en arrière les yeux ouverts ou fermés. (*c*) 3 jours après la cinquième procaïnisation les troubles orthostatiques ont presque disparu et cette amélioration dure encore après un mois.

sympyômes cérébrelleux ataxiques aprés fixation lombaire au moyen d un corset.

Note patiente, mise dans un corset, à éprouvé un soulagement des douleurs lombaires et un meilleur équilibre corporel.

Test de Mann la tendance qu avait montrée le sujet avant le traitement, à tomber en arrière les yeux ouverts avait disparu tandis que celle observée les yeux fermés est diminuée sans tout à fait disparaître

Test du nystagmus de position les mouvements horizontaux des yeux remarqués n ont présenté aucun changement aprés la fixation lombaire

Test du ynystagmus optocinetique et de pour suite d un objet en mouvement pas de changement.

Epreuve des index et épreuve du genou-talon le nombre d erreurs est diminué.

Epreuve des marionnettes aucune amélioration significative par l utilisation du croset, ni dans la pronation ni dans supination

Le résultat de ces examens montre bien que le fixation lombaire avec le corset apporte une certaine amélioration dans le fonctionnement de l équilibre et l etat ataxique du cervelet dont les symptômes sont observés aux membres supérieurs et inférieurs.

D Examens et évolution de l ataxie après la procaïnisation des muscles érecteurs lombaires.

Le résultat obtenu ici était meilleur que dans le cas d une fixation lombaire (ce qui signifie que le traitement par la procaïnisation lombaire est plus rationnel que la fixation lombaire).

Dans le cas qui nous préoccupe ici, le sujet a reçu cinq injections de 15 cc de solution à 1% de procaïne à raison d une fois par semaine

Avec chaque injection de procaïne la douleur lombaire était soulagée et la sensation de vertige diminuait. Parallèlement, les troubles orthostatiques, les mouvements anormaux des globes oculaires et la déviation des membres inférieurs se sont normalisés en même temps il ya eu une certaine amélioration dans l'ataxie des membres supérieurs.

Par exemple, dans le test de Mann, après la quatrième procaïnisation des muscles érecteurs lombaires, une légère oscillation latérale a été

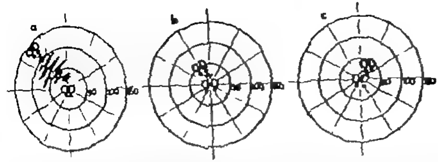

Fig. 2. Test du piétinement de Fukuda. (a) Avant traitement : déviation en avant gauche, accompagnée d'ataxie. (b) 7 jours après la quatrième procaïnisation : la distance de déviation comme l'angle de rotation vers la gauche ont diminué en même temps que les signes d'ataxie se sont réduits. (c) 30 jours après la cinquième procaïnisation : le piétinement s'est normalisé sans jamais s'aggraver de nouveau pendant le mois qui suivait.

servée les yeux ouverts au lieu de la tendance à tomber en arrière les yeux ouverts ou fermés, phénomène remarqué au début. Après la cinquième procaïnisation, les troubles orthostatiques avaient presque disparu et cette dernière amélioration dure encore après un mois. On voit Fig. 1 les enregistrement accélérométriques de chaque phase.

Dans le test du nystagmus spontané et de position, les petits mouvements horizontaux anormaux des globes oculaires qui étaient observés à la première visite ont disparu sans réapparaître après la troisième procaïnisation lombaire.

Quant à la déviation du piétinement accompagnée de signes d'ataxie notés avant le traitement, on a remarqué après la quatrième procaïnisation que la distance de déviation comme *l'angle de rotation vers la gauche ont diminué* en même temps que les signes d'ataxie se sont *réduits*. La cinquième procaïnisation terminée, le piétinement s'est normalisé sans jamais s'aggraver de nouveau pendant le mois qui suivait. On voit Fig. 2 le résultat schématisé du test du piétinement à chaque stade.

Pour les tests du nystagmus optocinétique et de poursuite d'un objet en mouvement, observation normale comme d'ailleurs avant le traitement.

Lors du premier examen, la pronation et la supination étaient maladroites aux membres supérieurs, surtout à gauche, si bien qu'elles étaient en état d'hypodiadochocinésis. Après la quatrième procaïnisation des muscles érecteurs lombaires elles se sont normalisées au membre supérieur droit, mais celles du membre supérieur gauche manquet encore d'habilité. Après la cinquième, elles sont devenues *tout à fait normales* à gauche comme à droite. Cette dernière amélioration se prolonge encore pendant un mois.

Dans l'épreuve des index, au lieu de 7 erreurs sur 10 essais enregistrées au début, on n'en a relevé 3 après la troisième procaïnisation et 2 après la cinquième.

L'épreuve de l'index-nez dont le résultat avait été normal avant le traitement ne changeait pas après la procaïnisation.

Dans l'épreuve du genou-talon, le nombre des erreurs qui était avant le traitement de 4 sur 10 essais pour la jambe droite et de 5 sur 10 pour la gauche, *diminuait au cours du traitement par* la procaïnisation à savoir après la cinquième procaïnisation la jambe droite n'a plus commis qu'une seule erreur ainsi que la jambe gauche.

La Fig. 3 montre deux courbes de fréquence de diminution du *réflexe H* aux membres inférieurs, l'une tracée en ▲ étant celle avant le traitement et l'autre *tracée* en ● étant celle après la cinquième procaïnisation. La courbe en ▲ montre qu'il y a suppression pour chaque fréquence aux stimuli électriques répétés, ce qui est *qualifié* par Ioku de troubles de type cérébelleux. Après la cinquième procaïnisation la suppression, notamment celle pour les fréquences basses comme on le voit, *s'est effacée et la* courbe est à peu près normale.

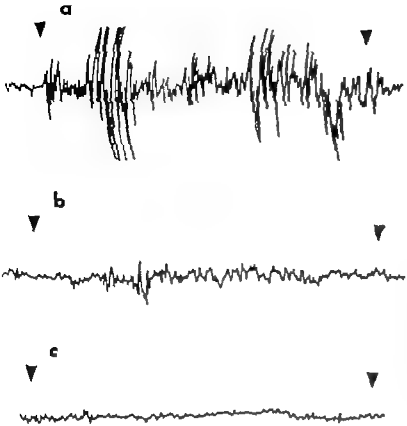

Fig. 1 Test de Mann (*a*) Avant traitement tendance à tomber en arrière avec les yeux ouverts et fermés. (*b*) 7 jours après la quatrième procaïnisation une légère oscillation latérale a été observée les yeux ouverts au lieu de la tendance à tomber en arrière les yeux ouverts ou fermés. (*c*) 30 jours après la cinquième procaïnisation les troubles orthostatiques ont presque disparu et cette amélioration dure encore après un mois.

Après la cinquième procaïnisation la suppression, notamment celle pour les fréquences basses comme on le voit, s'est effacée et la courbe est à peu près normale.

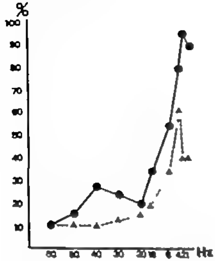

Fig 3 Courbes de fréquence de diminution du réflexe II aux membres inférieurs. ▲ Avant traitement ● après traitement.

Pour résumer ce qui précède, je crois pouvoir dire que la procaïnisation apporte une amélioration dans l'étant vertigineux, laquelle est d'ailleurs confirmée par les tests portant sur le fonctionnement de l'équilibre aussi bien que par le fait que les signes ataxiques cérébelleux observés aux membres supérieurs et inférieurs ont diminué parallèlement à cette amélioration.

Voici maintenant deux cas dans lesquels le sujet était traité pendant assez longtemps par la procaïnisation et dont l'observation de l'évolution est plus complète que celle du premier cas. L'anamnèse et le résultat du traitement de chaque cas sont décrits comme suit.

Cas 2 K.O., ♂ 53 ans, traumatisme cervical. Impliqué dans un accident de voiture, collision arrière, dans lequel le sujet n'a pas reçu de choc à la tête et n'a pas eu de troubles nerveux. Dès le troisième jour sont apparus la sensation vertigineuse, les douleurs nucales et la sensation de tête lourde. Au bout de 8 jours il avait des douleurs dans la région lombaire dont l'acuité allait augmentant avec la sensation vertigineuse. Malgré le traitement reçu dans une clinique, pas de soulagement, ce qui l'a conduit dans notre service.

L'ensemble des résultats de la première visite et après fixation lombaire par un corset est consigné dans le tableau I.

Après traitement par la fixation lombaire au moyen d'un corset les douleurs lombaires et la sensation vertigineuse sont soulagées et le résultat des tests orthostatiques et du piétinement de Fukuda s'est amélioré. D'après les tests, épreuve des index, épreuve de l'index-nez, épreuve des marionnettes, épreuve du genou-talon, on peut dire qu'il existe une certaine amélioration dans l'ataxie.

Les résultats mentionnés précédemment nous ont conduit à essayer sur ce malade un traitement par procaïnisation lombaire qui nous paraissait valable. Nous avons donc procédé à neuf injections de 15 cc de solution à 1% de procaïne, à raison d'une fois par semaine, de la région lombaire droite. On en voit le résultat dans le tabeau I. A quelques différences près chaque procaïnisation à apporté une amélioration tant dans le fonctionnement de l'équilibre que dans l'ataxie cérébelleuse.

Bien que l'efficacité de la procaïnisation ne soit pas aussi visible dans ce cas ci que dans le cas précédent, il est toujours constaté que chaque test a donné un meilleur résultat assez significatif pour pouvoir confirmer que le traitement par la procaïnisation est digne d'être adopté.

Cas 3 K.M., ♀ 26 ans, traumatisme cervical. Accident de voiture, collision arrière, le patient garde la conscience claire bien qu'il ait reçu un léger choc derrière la tête. Dès le lendemain sont apparues des sensations de contractures de la région cervicale et de tête lourde. Au bout de 8 jours il commençait à se plaindre de douleurs lombaires en même temps que sont apparues sensations vertigineuses (titubations) céphalées, douleurs nucales.

Après la fixation lombaire par un corset le vertige et les douleurs lombaires ont diminué (Tableau II). Amélioration dans le résultat des tests d'orthostatisme et du piétinement. La pronation et la supination des membres supérieurs n'ont pas retrouvé leur habileté restant toujours en état d'hypodiadochocinésie. Il y a eu une amélioration dans l'épreuve des index et de l'index nez mais pas de changement significatif dans l'épreuve du genou-talon.

Tableau I

Test de Mann tendance à vaciller ou à tomber avec les yeux soit ouverts soit fermés, + vacillement ou chute lorsque les yeux sont fermés, ± léger vacillement les yeux fermés qui n'aboutira pas à la chute; − normale

Nystagmus spontané et de position − normal

Epreuve des index, épreuve de l'index-nez, épreuve du genou-talon Sur 10 essais qui constituent le dénominateur le nombre d'erreurs représente le numérateur Par conséquent 7/10 dans le tableau signifie qu'il y a eu 7 erreurs sur 10 essais. G, main gauche; D main droite; hypo, hypodiadochocinésie

Anamnèse et examen		Changement des fonctions d'équilibre et des symptômes cérébelleux à la suite du traitement par la procaïnisation des muscles érecteurs lombaires			
		Avant traitement		Après traitement	
		Sans corset	Avec corset	7 jours après 4[e] procaïnisation	7 jours après 5[e] procaïnisation
Lombago		+	±	+	±

Nystagmus spontané et nystagmus de position			−	−	−
Test du piétinement de Fukuda					
Direction de la déviation		Droite	Gauche	Droite	Droite
Distance		50 cm	80 cm	20 cm	30 cm
Angle de rotation de l'axe du corps		30°	90°	20°	10°
Ataxie			±	+	±
Nystagmus optocinétique		Hypo-nystagmus	Pas de changement	Pas de changement	Légère amélioration
Epreuve des index		10/10	6/10	7/10	6/10
Epreuve de l'index-nez	D	10/10	6/10	7/10	7/10
	G	10/10	7/10	8/10	7/10
Epreuve des marionnettes	D	Hypo	Hypo	Hypo	Hypo
	G	Normal	Normal	Normal	Normal
Epreuve du genou-talon	D	2/10	1/10	2/10	1/10
	G	3/10	2/10	2/10	2/10

Les observations mentionnées antérieurement nous ont permis de penser que la procaïnisation de la partie douloureuse des lombes pouvait être un traitement valable du vertige et de l'ataxie dans ce cas. Nous avons donc procédé à cinq injections de 20 cc de solution à 1 de procaïne à raison d une fois par semaine. On voit l'effet de ce traitement indiqué en comparaison avec les états antérieurs dans le tableau II La sensation vertigineuse, les douleurs lombaires ont été soulagées par ce traitement. Bien qu encore insuffisante une amél oration a été apportée dans les tests d'équilibre Je crois aussi pouvoir dire que l'ataxie est elle aussi en voie de guérison après ce traitement. Il est particulièrement remarquable que le nombre des erreurs dans les épreuves des index ou de l'index nez soit diminué de presque la moitié.

Des expériences de ces trois cas nous avons tiré les remarques suivantes

— les troubles du fonctionnement de l équilibre et de l'ataxie cérébelleuse qu on observe habituellement dans le cas de vertige traumatique accompagné de douleurs lombaires peuvent être traités efficacement par la procaïnisation de la partie douloureuse des lombes.

— on peut adopter ce traitement lorsque la *fixation* lombaire au moyen d'un corset apporte une amélioration dans le fonctionnement de l'équilibre et un soulagement dans l'ataxie cérébelleuse

— bien qu il soit efficace ce traitement ne peut pas être *déclaré* la dernière thérapeutique possible du vertige traumatique pour lequel d'autres traitements seront à envisager

Tableau II

Test de Mann + + Tendance à vaciller ou à tomber avec les yeux soit ouverts soit fermés + vacillement ou chute lorsque les yeux sont fermés ± léger vacillement les yeux fermés qui n aboutira pas à la chute − normale

Epreuve du genou-talon	D	1/10	1/10	1/10
	G	1/10	1/10	1/10

Les considérations que nous avons faites sur ces trois premiers cas nous ont conduit a essayer d accompagner notre traitement d une autre thérapeutique Ainsi dans le quatrième cas que nous allons maintenant considérer le patient va être traité conjointement par la procaïnisation et par la traction des lombes. Car malgré son efficacité momentanée la procaïnisation n a apporté, dans notre dernier cas, qu un effet peu durable Le renouvellement de la procaïnisation, en outre nous a semblé avoir peu de chance de pouvoir prolonger l effet initial. Nous avons été pour ainsi dire obligé d adopter un autre traitement

Cas 4 I H., ♂ 24 ans, traumatisme cervical. La voiture du patient a été tamponnée par celle qui suivait. Au moment de l accident il n a pas eu conscience du coup qu il a reçu à la tête sans avoir perdu connaissance Dès le lendemain de l accident la nausée les douleurs nucales sont apparues. Au bout d environ un mois il a commencé à se plaindre de douleurs lombaires droites de vertige (sensation de vacillation corporelle), de mal de tête et de sensation de tête lourde Tous ces symptômes ont été améliorés par une thérapeutique vitaminée *B1 B12* et A T P Néanmoins, la reprise des douleurs lombaires droites, cervicales, accompagnées de vertige et d une démarche ébrieuse l amène à notre clinique ou il est hospitalisé

La fixation des lombes avec un corset a apporté chez notre sujet un soulagement de son vertige, de sa sensation de titubation et une amélioration dans le résultat des tests de la fonction d équilibre et de l ataxie cérébelleuse (Tableau III)

Partant des résultats des observations précé-

dentes nous avons pensé convenable de pratiquer un traitement par la procaïnisation de la partie douloureuse des lombes et nous avons procédé à l'injection de solution à 1 % sous un volume de 20 cc au total dans le lombe droit 10 cc au niveau de L3 10 cc au niveau de L4 (Tableau III, Fig. *4a, b* et *5a, b*)

Comme dans les trois cas précédents la procaïnisation des muscles érecteurs lombaires a apporté dans ce quatrième cas une amélioration des tests examinant la fonction de l'équilibre et un soulagement de l'état ataxique cérébelleux. Mais l'effet de la procaïnisation dans ce cas était d'une durée tellement courte que le sujet retombait dans l'état antérieur deux jours après l'injection. Nous avons quand même essayé encore trois procaïnisations successives qui n'ont pas changé les résultats. Nous avons donc été obligé d'employer un autre traitement que celui par procaïnisation et nous avons choisi la traction des lombes. Le sujet était mis sur un lit incliné, recevant une traction de 6 kilos continuellement pendant les dix premiers jours, et huit heures par jour pendant les dix jours suivants. A la fin de ce traitement notre patient a témoigné d'un soulagement des douleurs lombaires et du vertige. A telle enseigne qu'à la longue il ne s'en plaignait presque plus. Voici le résultat des examens portant sur la fonction d'équilibre, il est identique à celui obtenu 20 minutes après la procaïnisation mais avec cette différence que cette fois l'effet du traitement dure plus longtemps. Les examens effectués après un recul de 20 jours sont consignés dans le tableau III et Fig. *4a, c* et *5a, c*. Nous pouvons dire que dans ce cas la traction des lombes a pu apporter un

Les considérations que nous avons faites sur ces trois premiers cas nous ont conduit a essayer d accompagner notre traitement d une autre thérapeutique Ainsi *dans le quatrième cas que* nous allons maintenant considérer le patient va être traité conjointement par la procaïnisation et par la traction des lombes. Car malgré son *efficacité momentanée*, la *procaïnisation n a* apporté, dans notre dernier cas, qu un effet peu durable Le renouvellement de la procaïnisa tion en outre, nous a semblé avoir peu de chance de pouvoir prolonger l effet initial Nous avons été pour ainsi dire obligé d adopter un autre traitement

Réflexe H	2	2	0	3	7 cas

dans le chapitre précédent, ainsi qu'à d'autres cas examinés, ce que je pense sur l'efficacité, comme traitement du vertige traumatique accompagné d'ataxie cérébelleuse, de la procaïnisation des muscles érecteurs lombaires.

— La procaïnisation des muscles érecteurs lombaires est-elle efficace parmi les autres thérapeutiques possibles sur la région lombaire, comme traitement du vertige et de l'ataxie *dans les cas de vertige traumatique* accompagné de douleurs lombaires et de symptômes cérébelleux ?

Abstraction faite de différence de degré, les quatre cas exposés antérieurement montrent que l'injection de procaïne dans la région douloureuse lombaire peut apporter un soulagement ou une amélioration au vertige et à l'ataxie dont souffraient tous les sujets.

Nous avons essayé d'objectiver *les suites de la* procaïnisation pratiquée sur 28 cas, y compris les quatre cas déjà examinés, qui ont en commun cette particularité que tous les sujets se plaignent de douleurs unilatérales ou de prédominance unilatérale à la région lombaire en même temps que de vertige, en effectuant plusieurs test portant sur la fonction de l'équilibre et sur les symptômes cérébelleux ainsi qu'en interrogeant les sujets sur leur vertige. A l'issue de nos examens nous avons pu constater l'effet suivant : la procaïnisation apporte dans la plupart des cas (21 sur 28 cas examinés) un soulagement au vertige, pour la plupart ils se plaignaient d'une certaine sensation de chancellement. Dans un certain nombre de cas il existe une restitution ad integrum. Il n'y a que 7 cas où elle n'a rien changé au vertige dont souffrait les sujets. Il est à remarquer toutefois qu'aucun cas n'a présenté d'aggravation de l'état vertigineux.

Les considérations statistiques sur l'évolution du résultat des examens de la fonction de l'équilibre observée à la suite de la procaïnisation sont consignées dans le tableau IV.

Nous croyons pouvoir dire que la procaïnisation de la partie douloureuse des lombes est un traitement *efficace* du vertige traumatique accompagné des douleurs lombaires et de *symptômes cérébelleux*. Il est en particulier remarquable de noter que le vertige ne se soit jamais aggravé à la suite de la procaïnisation. Il en est de même quant aux résultats des examens de la fonction d'équilibre et des symptômes cérébelleux. A ce propos il n'est pas superflu de rappeler le rapport de Hinoki et al. (1967) qui notait que la procaïnisation de la partie douloureuse du cou pouvait aggraver le vertige et l'ataxie. D'après mes *propres expériences* l'injection au niveau du cou *a quelquefois apporté* des aggravations. Il semble que la *procaïnisation* lombaire soit plus sûre que celle du cou, bien que le *procédé soit identique* dans les deux cas.

— *Le résultat obtenu* dans les tests d'équilibre et d'ataxie cérébelleuse effectué après le traite-

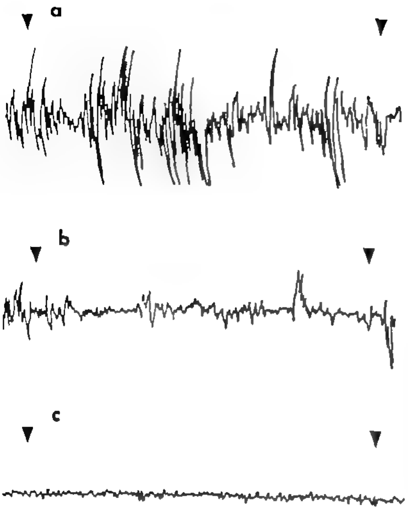

Fig 4 Test d orthostatisme (*a*) Avant traitement oscillations latérales [illegible] tendance à tomber soit les yeux ouverts soit les yeux fermés. (*b*) 20 minutes après la procaïnisation soulagement dans les douleurs des lombes et la sensation de vertige on voit une oscillation de la tête très diminuée. (*c*) Après 20 jours de tractions lombaires les mouvements violents de la tête ont pratiquement disparu.

soulagement des douleurs lombaires, du vertige, et une amélioration générale a quelques différences près selon les tests intérrogeant la fonction de l équilibre ou les symptômes ataxiques cérébelleux observés aux membres supérieurs et inférieurs. Il faut remarquer comme nous l avons déjà dit que l effet de la traction était d une durée plus longue que celui de la procaïnisation

COMMENTAIRES

Je voudrais présenter ici, en me référant aux résultats obtenus dans les quatre cas considérés

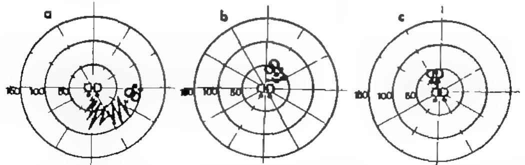

Fig 5 Test du piétinement de Fukuda (*a*) Avant traitement déviation en arrière droite accompagnée d ataxie. (*b*) 20 minutes après la procaïnisation la déviation vers l arrière du piétinement accompagnée d'ataxie s est amoindrie visiblement par la procaïnisation, l'ataxie est diminuée et la direction du corps vers l'arrière se trouve maintenant vers l'avant. (*c*) Après 20 jours de tractions lombaires il reste encore une légère déviation vers l'avant gauche mais [illegible] résultat obtenu ici est meilleur que celui obtenu 20 minutes après la procaïnisation, les symptômes d'ataxie observés pendant le piétinement ayant complètement disparu.

Les considérations statistiques sur l'évolution du résultat des examens de la fonction de l'équilibre observée à la suite de la procaïnisation sont consignées dans le tableau IV.

Nous *croyons pouvoir dire* que la procaïnisation de la partie douloureuse des lombes est un traitement efficace du vertige traumatique accompagné des douleurs lombaires et de symptômes cérébelleux. Il est en particulier remarquable de noter que le *vertige ne se soit* jamais aggravé à la suite de la procaïnisation il *en est de même quant* aux résultats des examens de la fonction d'équilibre et des symptômes cérébelleux. A ce propos il n'est pas superflu de rappeler le rapport de Hinoki et al. (1967) *qui* notait que la procaïnisation de la partie douloureuse du cou *pouvait* aggraver le vertige et l'ataxie. D'après mes propres expériences l'injec*tion au niveau* du cou a quelquefois apporté des aggravations. Il semble que la procaïnisation lombaire soit plus sûre que celle du cou, bien que le procédé soit identique dans les deux cas.

— Le résultat obtenu dans les tests d'équilibre et d'ataxie *cérébelleuse effectué* après le traite-

Tableau V *Corrélation entre le changement des réflexes d'orthostatisme par fixation lombaire (à l'aide d'un corset) et par la procaïnisation des muscles érecteurs lombaires*

Analyse de 19 cas de traumatismes cervicaux

	Procaïnisation		
Corset	Améliora tion	Pas changement	Détériora- tion
Amélioration	13		0
Pas changement	4	0	0
Détérioration	0	0	0

ment par fixation des lombes au moyen d un corset peut il être un indice pour employer le traitement par procaïnisation ?

Dans un article publié antérieurement j'ai rapporté que la plupart des cas de vertige traumatique accompagné de douleurs des lombes pouvait être efficacement traité par le port d un corset qui pouvait apporter un soulagnement du vertige et une amélioration dans la fonction orthostatique (17 cas d amélioration sur 21) tandis que le corset ne pouvait rien changer dans le cas ou il n existait pas de douleurs lombaires (15 cas sans changement sur 22) (Ushio 1970) Ce fait a été confirmé par le résultat que nous avons exposé ci-dessus. On a observé une amélioration dans l état de vertige et de la fonction orthostatique due au port du corset dans 15 cas sur 19 lorsqu il existait des douleurs lombaires, il en est de même pour l évolution des symptômes cérébelleux (14 cas sur 19) Dans 5 cas il n y a pas eu de changement Les tableaux V et VI rendent compte de ces résultats. Pour savoir si le traitement par procaïnisation lombaire est ou non adaptable, le résultat satisfaisant obtenu par le port du corset dans les examens d équilibre et d ataxie cérébelleuse est un bon indice

— Comparaison des effets thérapeutiques, sur le vertige et le déséquilibre du corps y compris les symptômes cérébelleux, de la procaïnisation lombaire et cervicale

Lorsqu un individu est atteint d un traumatisme cervical il se produit des lésions fonctionnelles ou organiques des tissues de soutien mous cervicaux et lombaires provoquant une hypertonie de ces tissus. On a déjà rapporté, Hinoki (1970) Ushio (1970 1971), que cette hypertonie était une des plus importante cause de l'apparition du vertige et de l ataxie de l'équilibre qui accompagne le traumatisme cervical. Le mécanisme par lequel apparait le vertige dans les deux cas a peu près identiques est que le tissu mou de soutien cervical ou lombaire constitue un rapport détente — câble avec l hypothalamus et le tronc cérébral et que cette relation prend part dans l apparition des vertiges et de l ataxie. Les points de dissemblance proviennent de la fréquence de l apparition des symptômes cérébelleux qui est plus élevée dans le cas d'hypertonie du tissu de soutien mou cervical d une part, d autre part de la fréquence de guérison de l ataxie cérébelleuse qui est plus élevée par la fixation des lombes par un corset. On peut conclure que le propriocepteur cervical ou lombaire joue un rôle associé avec le cervelet dans l apparition du vertige du traumatisme cervical avec prédominance du propriocepteur lombaire Ce dernier cas va illustrer notre propos.

Cas 5 Y.A., ♂ 33 ans, traumatisme cervical La voiture du patient a été tamponnée. Il n a pas pris conscience du coup qu il reçu à la tête tout en gardant une conscience claire Dès le deuxième jour après l'accident sont apparus nausées, douleurs cervicales et un sentiment de tête lourde au bout d un mois successivement un lumbago droit et une sensation vertigineuse se

font sentir. L'injection de procaïne dans la partie affectée du cou a eu pour effet de soulager les douleurs cervicales et d'améliorer le vertige et les troubles de l'équilibre. Par contre elle se montre peu efficace pour guérir l'ataxie cérébelleuse existante.

L'effet thérapeutique de la procaïne a perdu son efficacité en 24 heures. C'est pourquoi nous avons alors effectué la procaïnisation du lombe droit qui a amené la disparition des douleurs lombaires et un soulagement très visible dans la sensation de vertige.

Ce résultat nous permet de dire que la procaïnisation des lombes, à la différence de celle du cou, a un effet non seulement sur le résultat des examens portant sur la fonction de l'équilibre mais aussi sur l'amélioration de l'ataxie cérébelleuse. Ce résultat suggère que la procaïnisation cervicale dans ces cas bien qu'elle soit souvent utilisée, a une certaine limite.

Ces résultats ont été confirmés dans 7 autres cas identiques. Les patients se plaignaient de vertige, de douleurs cervicales et lombaires et présentaient des symptômes de la lignée cérébelleuse. Nous avons comparé les résultats obtenus après procaïnisation cervicale et lombaire avec un plus grand nombre de bons résultats après procaïnisation lombaire. Ce fait pourrait s'expliquer en partie parce que le propriocepteur lombaire est lié étroitement non seulement au tronc cérébral mais aussi au cervelet et que par conséquent les troubles orthostatiques et de la déviation du piétinement, tous les deux d'origine cérébelleuse, peuvent être supprimés par cette intervention. Cette hypothèse ne se contredit pas avec le fait que cette procaïnisation, par comparaison avec celle du cou, agit beaucoup plus efficacement sur les symptômes cérébelleux observés aux membres supérieurs et inférieurs. Pour ce qui est de l'effet exercé sur le nystagmus optocinétique par la procaïnisation cervicale et lombaire nous ne pouvons établir de comparaison en constatant que l'effet de la procaïnisation lombaire sera moindre sur le nystagmus que sur l'ataxie des membres supérieurs et inférieurs. Ce résultat permet de penser que les liaisons du propriocepteur lombaire d'une part avec le système des mouvements oculaires et d'autre part avec le réflexe spinal ne sont pas équivalentes mais qu'au contraire il est plus étroitement lié au système de réflexe spinal.

C'est sur l'ataxie cérébelleuse que la procaïnisation lombaire et cervicale diffère le plus. L'effet de la seconde donne sur l'ataxie cérébelleuse un résultat moindre que la première (Tableau VII).

Il faudra tenir compte de ces données lors du traitement du vertige et de l ataxie dans les cas de traumatismes cervicaux il ne suffira pas de traiter ce type de vertige uniquement par procaïnisation du cou mais il y aura intérêt à employer celle des lombes plus fréquemment

— Limites thérapeutiques de la procaïnisation des muscles érecteurs lombaires Conduite à tenir

D après le résultat obtenu il est évident que la procaïnisation de la partie affectée des lombes agit efficacement sur le vertige dû au traumatisme cervical. Il est aussi vraisemblable qu elle améliore le résultat des tests de la fonction d équilibre et en particulier ceux d orthostatisme ainsi que la déviation des membres inférieurs, elle diminue en outre les symptômes cérébelleux observés aux membres supérieurs et inférieurs. Dans la situation actuelle ou l on a pas encore de moyens puissants de guérir l ataxie cérébelleuse cette méthode sera digne d être employée plus fréquemment. La durée de l effet de la procaïnisation lombaire varie assez selon les cas Il y en a dans lesquels l effet d une seule injection dure plus de 8 jours et peut être prolongé plus longtemps par de nouvelles injections et d autres dans lesquels elle n a qu un effet assez court qui ne peut être prolongé par une nouvelle injection. Notre but à long terme sera de surmonter ce défaut A ce sujet nous avons fait deux ou trois expériences dont nous allons exposer ici l essentiel. La première consiste à mélanger lors de la procaïnisation des lombes, à la solution de procaine de la Vitamine B ou du Stéroïd (Rindéron) Ce mélange à comme effet efficace de prolonger l effet de la procaïnisation, si bien que maintenant nous utilisons habituellement une solution à 1 % de procaïne mélangée à 2 mg de Stéroïd Mais ce précédé n est pas efficace dans les cas ou l'effet de la procaïnisation ne dure pas plus de quelques jours et ne peut être prolongé par des séries de procaïnisations. Ces derniers cas nous obligent alors à employer d autres procédés. Nous avons adopté le traitement par traction lombaires. A ce propos il faut rappeler que la traction cervicale doit être *évitée au début,* comme nous l avons souvent remarqué Ce conseil se fonde sur le fait que ce traitement pratiqué sur des sujets dont le traumatisme était récent provoquait très souvent une aggration du vertige et de l'ataxie. Il s appuie sur les résultats des examens expérimentaux sur l'animal montrant que le traumatisme cervical s accompagne au début de déchirures, d hémorragies et de dilatations du tissu mou de soutien cervical. Il en est autrement dans les cas ou le traumatisme est plus ancien, dans ces cas la traction du cou convenablement chargée peut exercer une bonne influence sur le vertige et l ataxie Hinoki (1969) *confirme ces résultats On peut aussi exercer une* traction des lombes dans ce cas je m impose les deux règles suivantes pour exercer cette traction

1 N'utiliser cette technique que dans le cas où le traumatisme est ancien ou dans les cas où le sujet se plaint de lumbago dans les jours qui suivent l accident.

2 N appliquer cette technique que dans les cas ou la procaïnisation de la partie douloureuse des lombes s est montrée éphémère et sans effet après d autres procaïnisations.

Je voudrais de toute façon m abstenir de présenter une conclusion définitive faute d expérience assez nombreuses pour le faire au sujet de la charge à donner et au moment d effectuer ce traitement Si le traitement pour l hypertonie du tissu de soutien mou cervical est applicable à l hypertonie du tissu mou de soutien lombaire, la stimulation de la partie douloureuse des lombes par ondes basses fréquences, la cathode étant placée à la partie douloureuse ou le badigeonnage de paraffine mérite d être essayés. Cette thérapeutique est une de nos préoccupations futures.

Nous avons constaté expérimentalement que le vertige traumatique s accompagne en même temps d une anomalie fonctionnelle du tronc cérébral et du cervelet (Ushio 1970 1971 1973). En vue de guérir l anomalie fonctionnelle du tronc cérébral la Centrophénoxine (Lucidril) et la CDP choline (Nicholin) ont été utilisées Les résultats de leur efficacité ont été consignés dans les travaux d Hinoki et al. (1967) et Ushio et *al (1970) Pour les cas accompagnés de troubles* du tronc cérébral il sera raisonnable d utiliser

ce médicament même si l'on est en présence de symptômes cérébelleux. Mais étant donné l'insuffisance d'efficacité au cours de nos propres expériences, du *traitement* par *l'utilisation exclusive* de ces médicaments, il est préférable d'utiliser en même temps un autre procédé intéressant les lombes par exemple la procaïnisation. L'utilisation associée médicament + procaïnisation donne un meilleur *résultat* que la procaïnisation seule. Il est nécessaire néanmoins d'avoir une plus grande expérience à ce sujet.

RÉSUMÉ

I. Nous avons pris pour sujets à examiner ceux souffrant de vertige traumatique accompagné de douleur lombaire (lumbago etc.) en même temps que de symptômes cérébelleux frustes. Nous avons procédé à un traitement par injection de procaïne dans la région douloureuse lombaire. Nous avons obtenu les résultats suivants

— il y a un grand nombre de patients qui ont témoigné à la suite de la procaïnisation de la partie douloureuse lombaire de la disparition du lumbago et d'un soulagement, voire même de la disparition du « vertige »

— pour un grand nombre de cas le résultat des examens portant sur le fonctionnement de l'équilibre (surtout du test d'orthostatisme et celui de déviation des membres inférieurs – test du piétinement) s'améliore en même temps que les symptômes cérébelleux frustes observés aux membres supérieurs et inférieurs s'amoindrissent.

— Il faut tout de même distinguer deux cas dans l'un, l'injection a un effet relativement prolongé qui peut être encore poursuivi par la répétition de la procaïnisation, dans l'autre on observe le contraire la procaïnisation n'ayant qu'une courte vie et ne pouvant être améliorée par une autre injection. Dans ce dernier cas nous avons essayé comme traitement supplémentaire la traction lombaire par laquelle le vertige a été efficacement supprimé

— lors de la fixation des lombes par un corset, le fonctionnement orthostatique se trouve amélioré et les symptômes cérébelleux frustes diminués (vérification par les épreuves des index, de l'index-nez et des marionnettes), alors la procaïnisation des lombes est à adopter comme traitement du vertige traumatique

II. Dans le cas où nous avons pris comme sujets à traiter ceux qui souffraient de vertige traumatique avec des douleurs cervicales et lombaires nous avons effectué les procaïnisations des parties affectées du cou et des lombes. Les résultats suivants ont été obtenus

— les procaïnisations du cou et des lombes ont servi toutes les deux à améliorer l'état de vertige en même temps que les résultats du test d'orthostatisme et de déviations des membres inférieurs (test du piétinement) dans bien des cas.

— en ce qui concerne les symptômes cérébelleux frustes la procaïnisation du cou était peu efficace, par contre celle des lombes s'est trouvée être efficace pour leur amélioration.

Les résultats obtenus semblent appuyer l'hypothèse que nous avons posée et que nous avons défendue dans nos publications suivant laquelle l'hypertonie du propriocepteur lombaire, tout en agissant sur l'anomalie fonctionnelle non seulement du tronc cérébral mais aussi du cervelet, participe à la genèse de l'ataxie de l'équilibre.

Les mêmes résultats semblent indiquer que la procaïnisation des muscles érecteurs lombaires mérite d'être employée pour supprimer le « vertige » dans les cas qui nous concernent.

TUBING AS A TREATMENT FOR RECURRENT INFANT SUPPURATIVE OTITIS MEDIA

Yoshiki Hattori

Gifu, Japan

Abstract (1) The details described below have evidenced that the tubing therapy is an influential treatment for the recurrent infant suppurative otitis media. The tube with a beveled head and split shank is very convenient and effective for the treatment since it is not only easily inserted but also easily removed, preventing it from migration into the tympanum. (2) The treatment must promote the drainage of discharges through the infant auditory tubes which are thick and short and improve the ventilation of the middle ear cavity half permanently (3) According to the author's experience, the spontaneous extrusion of the ideally set tube after 2 or 3 months is a sign of a perfect cure of this disease.

Since tympanostomy with a plastic tube was introduced in 1959 by Armstrong, many papers on this subject have been published and it has been generally recognized as an important otologic treatment. Nowadays, however the treatment is mainly applied to nonsuppurative middle ear diseases. The author has obtained good results by applying it to suppurative middle ear diseases of infants, namely to recurrent infant suppurative otitis media.

In many cases of infant suppurative otitis media, a drainage made by a myringotomy is generally closed after 2 or 3 days and the retention of purulent discharge occurs again in the middle ear cavity On the other hand there are many cases of infant suppurative otitis media whose tympanic membrane seems to be cured by using antibiotics, but the disease recurs spontaneously by a slight upper airway infection. However if any perforation even a very small one like a pin hole remains after the pus has disappeared a recurrence of the inflammation rarely occurs, or even if a recurrence does occur it is mostly slight and can be cured in a short period From a clinical viewpoint of such a schematic process of suppurative otitis media of infants the author presumed that the promotion of continuous ventilation of the middle ear cavity through a tympanostomy tube could prevent a recurrence of suppurative otitis media of infants.

SHAPE OF THE TUBE

Armstrong, Per Lee Silverstein and others described an indication of the myringotomy with a plastic tube mainly for chronic nonsuppurative middle ear diseases. Therefore various shapes of the tube have been developed in order to be able to fix a tube, long and tight, through the tympanic membrane between the external meatus and tympanic cavity However in cases of infant recurrent suppurative otitis media, the tube must be not only easily inserted but also easily removed because it drops out often spontaneously according to the cure of the disease. According to the author's experience 3 months are sufficient to keep the tube on the drumhead in order to obtain a perfect cure Thus, a new type of tube was designed in 1971 by the author

Fig. 1 illustrates the new polyethylene tube 10 mm long and 1 mm in diameter with a beveled head like a tympanum puncture needle The tube can be inserted in a needle hole after a puncture or through a pin hole perforation which is ready to close The split shank protects the tube from dropping into the tumpanum and from obstruction by blood clot or secretion.

Fig. 1 Polyethylene tube which is used by the author (30 mm long and 1 mm in diameter).

APPLICATION OF THE TUBE

1 *Appropriate stage for tubing*

First of all, customary treatments for the suppurative otitis media must be performed. Aural discharge usually disappears in a week. At this stage, if any perforation remains, a tube should be inserted through the perforation. If the perforation is greater than the diameter of the tube, the insertion should be postponed untill the perforation decreases in size somewhat smaller than the tube diameter. Even in cases with a perforation which has been closed, a tympanum puncture often reveals a small amount of mucous secretion, so that a tube should be inserted through the needle hole made by the puncture on the drumhead.

2. *Anesthesia*

Local anesthesia is sufficient in most cases, namely an existing perforation of a drumhead or a needle hole by a puncture supplies a sufficient anesthesia through an ear bath with 4–8% Lidocain solution.

3. *Site of the tube application*

The anterior inferior quadrant is generally chosen as the site of application of the tube.

4. *Complication*

Complications that had been reported such as bleeding, obstruction of the tube were encountered but no new complications were observed.

5. *Microscope*

An operating microscope is necessary to perform a tube application efficiently

CASES

The tubing was performed in 36 ears of 24 cases among 126 cases of infant suppurative otitis media, admitted from January 1971 to December 1973. They were infants from 6 months to 2 years of age averaging 1 year and 1 month.

Each one of the 24 cases had a previous history of recurrent suppurative otitis media treated with several myringotomies, tympanum punctures and antibiotics.

In 10 ears of 7 cases, mastoid antrums were still not clear radiographically although improvements were revealed in tympanic membranes. In 4 ears of 2 cases, multiple resistance was present in the sensitivity test of antibiotics. Two cases had significant allergic disposition. Two cases were affected measles during otitis media. Two cleft palate cases were included. The following 24 cases received the tubing therapy i.e. infant suppurative otitis media which recurred often in spite of the customary treatments such as intensive use of antibiotics, myringotomy, tympanum puncture, use of steroid or enzyme and γ-globulin injections.

RESULTS

1 After the tube was set, 21 cases were affected with upper respiratory infection.

2. [illegible] ears of these 21 cases progressed satisfactorily without any aural discharge in spite of the upper respiratory infection which was cured after a few days. Then the tube was *extruded* spontaneously 2 or 3 months after the insertion and the drumhead showed a complete cure of the

RESPONSES OF CORTICAL VESTIBULAR CENTER PRODUCED BY STIMULATION OF VESTIBULAR NUCLEI AND VISUAL ASSOCIATION AREA IN THE CAT

Satoru Watanabe, Hiroyasu Jijiwa and Kazuo Itoh[1]

Institute of Equilibrium Research, Gifu University School of Medicine, Gifu, Japan

Abstract. (1) The cortical projection of the vestibular nuclei (LVN, MVN and IVN) was investigated by the evoked potential and unit discharge analyses in the cat anesthetized with alpha-chloralose and/or immobilized with gallamine triethiodide. (2) This projection field coincided well with that of the vestibular nerves, being principally contralateral by LVN stimulation but nearly symmetrical by either MVN or IVN stimulation. (3) Of 11 units responsive to vestibular nuclei stimulation, 6 reacted to stimulation of the visual association cortex (anterior part of the Clare-Bishop area). The response pattern of the cortical vestibular units by C-B stimulation was a sequence of excitation, inhibition and rebound. (4) Interaction of visual information with the cortical vestibular neurons was discussed.

Many studies have been published on the primary cortical vestibular projection area which rely on evoked potential methods or single unit analysis involving stimulation of the vestibular nerve in the monkey (Fredrickson et al., 1966 Schwarz & Fredrickson, 1971*b* Schwarz et al., 1973), the cat (Walzl & Mountcastle 1949· Kempinsky 1951 Anderssen & Gernandt, 1954 Mickle & Ades, 1954 Milojevic & St. Laurent, 1966 Landgren et al 1967 Sans et al 1970), the rabbit (Ödkvist et al 1973) and the guinea pig (Ödkvist et al., 1973). In some of these animals it has been found that the area is adjacent to actually within the face region of the somatosensory cortex. Moreover in the monkey and the cat, the vestibular cortex, unlike other primary sensory areas, receives a convergence both from the vestibular and the somatosensory projection. The monkey vestibular field has been found to respond to both vestibular and kinesthetic (joint movement) stimuli or deep muscle pressure (Schwarz & Fredrickson 1971*a*) It has also been reported that the vestibular and somatosensory convergence exists even in the primary relay station of the vestibular nerve, in the vestibular nuclei (Fredrickson et al., 1966*b*). The convergence in the vestibular nuclei has been confirmed on the bases of postural and oculomotor reflex findings. On the other hand, the bimodal characteristics of the cortical vestibular field, as suggested by Fredrickson et al. (1966*a*), may signify that the motor regulation and conscious spatial orientation have a highly developed hierarchy of functional differentiation. In the present experiments, one goal was to ascertain whether the area responding to stimulation of the vestibular nuclei and having the bimodal characteristics, corresponds with the vestibular field which has been hitherto investigated by stimulation of the vestibular nerve.

The vestibular field reportedly extends over the anterior supra- and the anterior ectosylvian gyri, or on a circumference around the descending limb of the anterior suprasylvian sulcus. This region is just adjacent to the visual association area, V_m (Sanides & Hoffman, 1968), also named the Clare–Bishop area (Clare & Bishop, 1954). Concerning interaction between vestibular and visual information, vestibular influences upon visual sensation were already reported by some investigators (Grüsser et al., 1960· Kornhuber & Fonseca, 1964 Horn & Hill, 1969 Grüsser & Grüsser-Cornehls, 1972, Denney &

[1] Present address. Department of Anatomy Gifu University School of Medicine, Gifu, Japan.

inflammation without any perforation or with only a small pinhole perforation

3 In 3 ears, the early extrusion of the tube occurred within a month One ear showed a recurrence of aural discharge although the perforation had already been closed once. In the other 2 ears, the perforation remained but the disease was cured (A tube inserted incompletely was often extruded within a few days. Such cases are omitted from this paper)

4 In 2 ears which had neither involvement of acute upper respiratory infection nor recurrence of aural discharge the tube was not extruded spontaneously even after 3 months. The tube was removed by the author

5 The tube was swept out by and carried away to the external meatus by the massive aural discharge in 9 ears.

DISCUSSION

The reason for the effectiveness of the tubing is summarized from these results in the following three points.

1 *Ventilation*

It can be said that the 22 ears did not show any recurrence of a suppurative inflammation despite the acute upper respiratory infection because of the continuous ventilation of the middle ear cavity through the tube It can also be said that the spontaneous extrusion of the ideally set tube after 2–3 months accompanied with healing of the otitis media is the best result of this treatment.

2. *Drainage*

There is no evidence of a healing acquired by drainage of pus through the tube in these 24 cases Therefore by the tubing discharges retained in the middle ear cavity must be swept out and drainaged through the infant thick and short auditory tube. Just as the liquid in a pipet drops out by removing a finger which covers the upper end of the pipet, i.e. the drainage should be done through the auditory tube by the insertion of the tube, but not through the inserted tube.

3 *Fuse effect*

If a suppurative inflammation occurs in the ear in which the tube is inserted, the tube is washed out to the external meatus by the massive purulent discharge thus the drainage of purulent discharge is accomplished and it has same effect of an early stage myringotomy Per Lee described that "Six infectious episodes were unresponsive to topical and systemic antibiotic therapy and terminated only after the tube was removed Inflammatory hyperplasia granulation, and obstruction to drainage were the pathologic features in these cases. In other words, the effect of an inserted tube is easy dropping out by an acute suppurative inflammation and it corresponds to the effect of a fuse in an electric circuit It can be said that the tube turns off or reduces an exacerbation of disease and helps a spontaneous healing of an infant who is disposed to recurrent suppurative otitis media

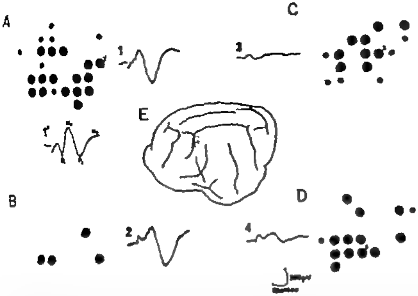

Fig 1 Distribution of cortical responses to electrical stimulation of vestibular nuclei. A, C and D distributions of responses to stimulation of contralateral LVN, MVN and IVN, respectively B ipsilateral LVN stimulation. Different-sized diameters of filled circles which respectively indicate (from larger to smaller) amplitude of each response is higher than 60 %, between 60–40 %, or lower than 40 % of maximal response for each stimulation. Unresponsive portions are indicated by open circles. Recording sites are shown by black dots in E. 1–4 typical evoked responses to each stimulation, the recorded sites of which are indicated by the same numbers in A–D. 1' response evoked on AI area to contralateral LVN stimulation. See text for details. Upward deflection indicates negativity in this and all following figures.

At the termination of each experiment, the animals were anesthetized with Nembutal and perfused with 10 % formalin solution from the carotid artery and the whole brain was removed for histological study. Frozen and/or celloidin sections of the brain were cut at every 30 μ, and stained by Nissl technique.

RESULTS

1 *Projection Fields of Vestibular Nuclei*

(a) *Lateral vestibular nucleus*

The cortical projection field evoked by stimulation of contralateral LVN (Fig. 1A) was found to lie around the descending limb of the anterior suprasylvian sulcus (SSS). The main responding area was in the anterior suprasylvian gyrus. A typical evoked potential consisted of an initial positive and negative sequence followed by a large, slow positive deflection. two or three ripple-like wavelets sometimes appeared in an asceding slope of the initial positive–negative deflection. The earliest peak latency of negativity measured was 9.0 msec at a part just rostral to the SSS. The maximal amplitude was obtained in this part, reaching as high as [illegible] μV in negative deflection and 160 μV in slow positive one. In the region caudal to the SSS, which overlapped the region of auditory I (A I) as described by Thompson et al. (1963), there was a characteristic response composed of a sequence of potentials consisting of small negative (N_1), a large positive (P_1), a large negative (N_2), a large positive (P_2) and a large slow negative (N_3) component. The respective peak latency of each component was 5.6 msec, [illegible] msec, 13.3 msec, 21.1 msec and 33.2 msec. Distribution of this type of potential with the initial negative (N_1) and positive (P_1) sequence followed by the typical triphasic response did not extend to the rostral region beyond the SSS anteriorly. Since the stria acustica runs along the LVN it might be simultaneously stimulated by the LVN

Adorjani, 1972). However investigation of the visual influences affecting vestibular sensation has been rarely reported except for one paper by Kornhuber (1972) But we do have some real life experience on the subject for example the fact that when a skilled ballet dancer in the course of a pirouette fixes his gaze upon some stationary object neither postrotatory nystagmus nor vertigo occurs (Fukuda & Tokita 1971). This is one noteworthy fact that encouraged the authors to investigate the underlying neural connection between the vestibular field and the visual association area Accordingly another goal of the present experiments was to make clear a direct connection and the interaction between the vestibular field and the visual association area.

MATERIALS AND METHODS

Experiments were performed on 14 cats weighing 2.4 kg to 4 0 kg. Eight were employed for estimation of the vestibular field six for unit analysis, and all were initially anesthetized with ketamine hydrochloride (Ketalar Parke Davis & Sankyo) 15–20 mg/kg administered intramuscularly Cannulae were inserted into the trachea for artificial respiration and the radial cutaneous vein for administration of drugs. The animals were placed in a stereotaxic frame and craniotomized to expose a part of the frontal cortex, the entire anterior suprasylvian and anterior ectosylvian gyri and a part of the visual cortex in the left hemisphere The cerebrospinal fluid was drained through a cisterna magna incision in order to reduce the movements of the brain To prevent drying, the exposed cortices were covered with 4 percent agar Ringer solution, except for a recording portion filled with liquid paraffin Body temperature was maintained by a heating pad Concentric needle electrodes with an outer electrode diameter of 1 0 mm and inner one of 0.5 mm and an interelectrode distance of 0 8 mm were used for stimulation These stimulating electrodes were inserted in the vestibular nuclei with the stereotaxic coordination modeled on the atlas of the cat brainstem (Berman, 1968) the lateral vestibular nucleus (LVN) P 7 L 4 depth −4 the medial vestibular nucleus (MVN) P 9 L 2.5 depth −3 the inferior vestibular nucleus (IVN) P 12, L 2.5 depth −4 Other stimulating electrodes were placed with naked eye on the visual association cortex, V_{aa} which lies on the medial bank of the middle suprasylvian sulcus (Clare–Bishop area, C–B), and on a macular region (middle portion of the area 17–18 border) and/or an upper part of the vertical meridian (anterior portion of the area 17 18 border) of the visual cortex. A stimulating square pulse of 0 01–0 05 msec duration at a frequency of 0 5–1 Hz was used and its intensity was varied from 1 to 30 V Before recording, the animals were re-anesthetized with alpha-chloralose (60 mg/kg) and/or immobilized with gallamine triethiodide (3 mg/kg/hr) Respiration was maintained artificially

Cortical evoked potentials were recorded monopolarly with a silver ball electrode from the pial surface of the anterior supra and ectosylvian gyri reference being made to the cranial skin detached from the skull. With the aid of a micromanipulator the electrode was moved with rectangular coordinates calibrated in millimeter units. The resulting evoked potentials of 40 successive stimuli were averaged by an ATAC 501 computer and photographed. In several experiments the depth potential profiles and unitary discharges were recorded with micropipettes filled with 1 5 M potassium citrate (resistance 3–10 meg ohms). The depth potentials were also averaged by computer while unitary discharges were stored on magnetic tapes, displayed on an oscilloscope and eventually filmed.

Electrolytic lesions were made at all stimulating sites. In order to confirm microelectrode tracks for the depth potential recording and unitary discharge analysis, the micropipette removed after recording was coated with china ink and reinserted into the cortex parallel together with but 1 mm apart from the recording track, so that direction of the electrode tracks could be proved histologically The depth from the cortical surface was read from a micrometer gauge on the micromanipulator

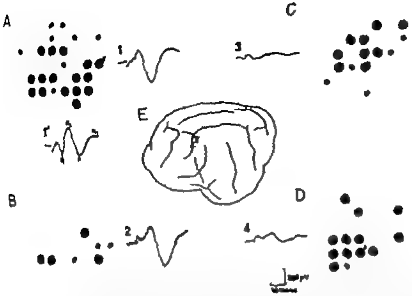

Fig. 1. Distribution of cortical responses to electrical stimulation of vestibular nuclei. A, C and D: distributions of responses to stimulation of contralateral LVN, MVN and IVN, respectively. B: ipsilateral LVN stimulation. Different-sized diameters of filled circles which respectively indicate (from larger to smaller) amplitude of each response higher than 60 %, between 60–40 %, or lower than 40 % of maximal response for each stimulation. Unresponsive portions are indicated by open circles. Recording sites are shown by black dots in E. 1–4: typical evoked responses to each stimulation, the recorded sites of which are indicated by the same numbers in A–D. 1': response evoked on AI area to contralateral LVN stimulation. See text for details. Upward deflection indicates negativity in this and all following figures.

At the termination of each experiment, the animals were anesthetized with Nembutal and perfused with 10 % formalin solution from the carotid artery and the whole brain was removed for histological study. Frozen and/or celloidin sections of the brain were cut at every 30 μ, and stained by Nissl technique.

RESULTS

1. *Projection Fields of Vestibular Nuclei*

(a) *Lateral vestibular nucleus*

The cortical projection field evoked by stimulation of contralateral LVN (Fig. 1A) was found to be around the descending limb of the anterior suprasylvian sulcus (SSS). The main responding area was in the anterior suprasylvian gyrus. A typical evoked potential consisted of an initial positive and negative sequence followed by a large, slow positive deflection, two or three ripple-like wavelets sometimes appeared in an ascending slope of the initial positive–negative deflection. The earliest peak latency of negativity measured was 9.0 msec at a part just rostral to the SSS. The maximal amplitude was obtained in this part, reaching as high as 80 μV in negative deflection and 160 μV in slow positive one. In the region caudal to the SSS, which overlapped the region of auditory I (A I) as described by Thompson et al. (1963), there was a characteristic response composed of a sequence of potentials consisting of small negative (N_1), a large positive (P_1), a large negative (N_2), a large positive (P_2) and a large slow negative (N_3) component. The respective peak latency of each component was 3.6 msec, 10 msec, 13.3 msec, 21.1 msec and 33.2 msec. Distribution of this type of potential with the initial negative (N_1) and positive (P_1) sequence followed by the typical triphasic response did not extend to the rostral region beyond the SSS anteriorly. Since the stria acustica runs along the LVN, it might be simultaneously stimulated by the LVN

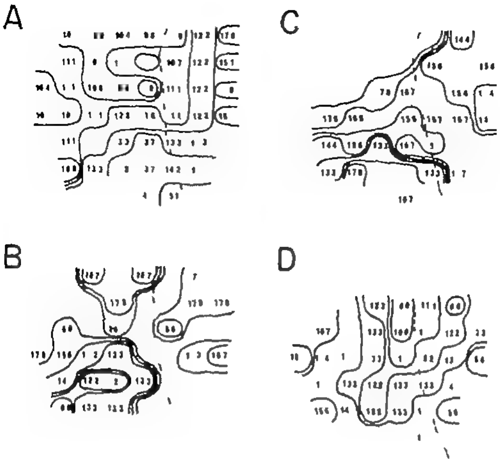

Fig 2 Contour map of latencies of evoked responses. A D same as in Fig. 1 Contour lines are drawn on the basis of the peak latencies of negative waves evaluated in msec. Dotted line indicates the suprasylvian sulcus.

electrode so this could possibly be an auditory response The second negativity (N_2) had a similar peak latency as the negativity of the triphasic typical potentials, seemingly derived from an analogous origin The contour map displaying topographical distribution of the peak latency of negativity (Fig. 2A) indicates that the region with shorter latency corresponds with the higher amplitude region rostral to the SSS In the region more lateral to A I the evoked responses took on the typical sequence of potentials, although they showed abruptly decreasing amplitudes.

With ipsilateral LVN stimulation the active region was found somewhat more lateral to the parts responding to contralateral LVN stimulation (Fig. 1B and Fig. 3A) The response was almost the same as for the contralateral one being formed by a triphasic sequence and having peak latencies of 11 1 msec for the negative and 20 0 msec for positive components in the shortest case The maximal amplitude was 30 μV and 160 μV respectively Topographical distribution of the peak latency and also of the amplitude of the negativity showed a slight difference between the ipsi- and contralateral responses, that is, the contralateral response was of shorter latency and of larger amplitude than the ipsilateral one. With the ipsilateral stimulation, the response with the largest amplitude and the shortest latency was elicited in more lateral region than with the contralateral one. This difference may be due to asymmetry of stimulating positions, but it is rather questionable whether a little difference in electrode positions could alter practically the active area even with stimulation of such high intensity as 20 V and duration of 0 03 msec. The evidence would imply that the variation originates from a characteristic of laterality

(b) Medial vestibular nucleus

The area activated by the MVN stimulation was found more lateral than by the LVN stimulation and located mainly rostral to the SSS (Fig. 1C and Fig. 3C). A typical potential consisted of triphasic small negative–positive and slow negative deflections (Fig. 1C–3). The maximal amplitude and the shortest latency of negativity measured was 60 μV and 13.3 msec, respectively.

(c) Inferior vestibular nucleus

The response evoked by IVN stimulation was characterized by two peaks of small negative and slow positive waves (Fig. 1D–4). The initial negative peak was 40 μV in amplitude and had a latency of 5.6 msec, and the second negative–positive sequence was 120 μV in amplitude. Topographical distributions of the magnitude of the second negative–positive sequence were shown in Figs. 1D (ipsilateral stimulation) and 3D (contralateral stimulation). The extent of the active region delineated by stimulation of IVN was more limited than that delineated by the LVN stimulation, but was almost as large as that by the MVN stimulation. The location of the active region by IVN stimulation was more lateral than by the MVN stimulation.

2. *Cortical Depth Distribution of Potentials*

The depth potential profiles illustrated in Fig. 4 are obtained by microelectrode inserted obliquely from the cortical surface to the lower bank of suprasylvian fold. The surface potential evoked by stimulation of contralateral LVN was distinguished by a negative wave with peak latency of 10 msec. As the electrode was advanced deeper from the surface, the negative wave diminished gradually up to a depth of 1 600 μ, while the preceding positive wave increased its amplitude and reached a maximum at depth of 000 μ. The phase reversal occurred at depths between 1 600 and 2 000 μ. At 3 000 μ, spike discharges appeared superimposed on the negative wave, and no further positive wave could be seen. At 4 000 μ, the spike activity was no longer seen and only the negative wave remained. With

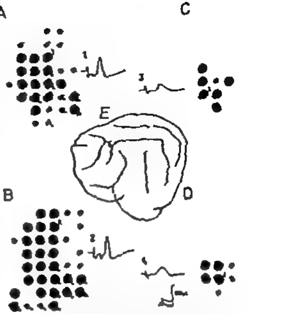

Fig. 3. Distribution of cortical responses to electrical stimulation of vestibular nuclei. A, C, D and B, distributions of responses to stimulation of ipsilateral LVN, MVN, IVN and contralateral LVN, respectively. Other was the same as in Fig. 1 except that the filled triangles indicate positive wave preceding the negative one, the larger triangles showing higher amplitude.

the ipsilateral LVN stimulation, the amplitudes of both peaks of the negative wave with the latencies of 9 msec and 14 msec decreased with the advance of the electrode, flattening at depths of 1 200 and 1 600 μ. At 3 000 μ and 4 000 μ the negative wave again reappeared, exhibiting a waveform similar to the surface potential. In this track, the unit response was not elicited by the ipsilateral LVN stimulation.

Initial triphasic and positive–negative–positive waves appeared within 3 msec after stimulation of the contralateral MVN and IVN. Since no significant changes in their phase and amplitude could be found up to the depth of 4 000 μ, the waves might be due to the afferent volleys. With MVN stimulation, the slow negative wave was seen after the initial changes. This slow negative wave, of which the peak latency was 11 msec and the amplitude was 60 μV, showed hardly any variation up to a depth of 800 μ. At 1 200 μ amplitude of the negative wave was lessened and subsequently a positive deflection with the peak

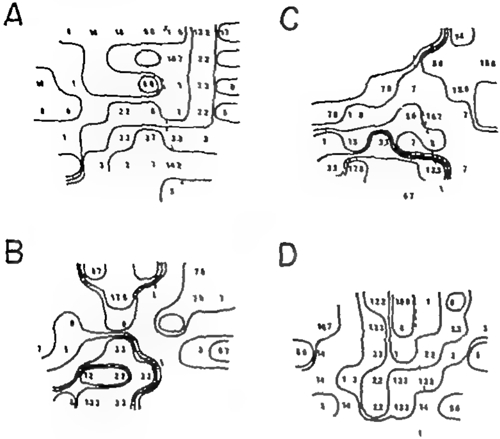

Fig. 2. Contour map of latencies of evoked responses. A–D same as in Fig. 1. Contour lines are drawn on the basis of the peak latencies of negative waves evaluated in msec. Dotted line indicates the suprasylvian sulcus.

electrode, so this could possibly be an auditory response. The second negativity (N_2) had a similar peak latency as the negativity of the triphasic typical potentials, seemingly derived from an analogous origin. The contour map displaying topographical distribution of the peak latency of negativity (Fig. 2A) indicates that the region with shorter latency corresponds with the higher amplitude region rostral to the SSS. In the region more lateral to A I the evoked responses took on the typical sequence of potentials, although they showed abruptly decreasing amplitudes.

With ipsilateral LVN stimulation the active region was found somewhat more lateral to the parts responding to contralateral LVN stimulation (Fig. 1B and Fig. 3A). The response was almost the same as for the contralateral one, being formed by a triphasic sequence and having peak latencies of 11.1 msec for the negative and 20.0 msec for positive components in the shortest case. The maximal amplitude was 30 μV and 160 μV respectively. Topographical distribution of the peak latency and also of the amplitude of the negativity showed a slight difference between the ipsi- and contralateral responses, that is, the contralateral response was of shorter latency and of larger amplitude than the ipsilateral one. With the ipsilateral stimulation, the response with the largest amplitude and the shortest latency was elicited in more lateral region than with the contralateral one. This difference may be due to asymmetry of stimulating positions, but it is rather questionable whether a little difference in electrode positions could alter practically the active area even with stimulation of such high intensity as 20 V and duration of 0.03 msec. The evidence would imply that the variation originates from a characteristic of laterality.

(b) *Medial vestibular nucleus*

The area activated by the MVN stimulation was found more lateral than by the LVN stimulation and located mainly rostral to the SSS (Fig. 1C and Fig. 3C). A typical potential consisted of triphasic small negative-positive and slow negative deflections (Fig. 1C-3). The maximal amplitude and the shortest latency of negativity measured was 60 μV and 13.3 msec respectively.

(c) *Inferior vestibular nucleus*

The response evoked by IVN stimulation was characterized by two peaks of small negative and slow positive waves (Fig. 1D-4). The initial negative peak was 40 μV in amplitude and had a latency of 5.6 msec, and the second negative-positive sequence was 120 μV in amplitude. Topographical distributions of the magnitude of the second negative-positive sequence were shown in Figs. 1D (ipsilateral stimulation) and 3D (contralateral stimulation). The extent of the active region delineated by stimulation of IVN was more limited than that delineated by the LVN stimulation, but was almost as large as that by the MVN stimulation. The location of the active region by IVN stimulation was more lateral than by the MVN stimulation.

2. *Cortical Depth Distribution of Potentials*

The depth potential profiles illustrated in Fig. 4 were obtained by microelectrode inserted obliquely from the cortical surface to the lower bank of suprasylvian fold. The surface potential evoked by stimulation of contralateral LVN was distinguished by a negative wave with peak latency of 10 msec. As the electrode was advanced deeper from the surface, the negative wave diminished gradually up to a depth of 1 600 μ, while the preceding positive wave increased its amplitude and reached a maximum at depth of 2 000 μ. The phase reversal occurred at depths between 1 600 and 2 000 μ. At 3 000 μ, spike discharges appeared superimposed on the negative wave, and no further positive wave could be seen. At 4 000 μ, the spike activity was no longer seen and only the negative wave remained. With

latency of 17 msec appeared Amplitude increased with advance of the electrode With the IVN stimulation, a monophasic slow positive wave was elicited and its amplitude was increased to the depth of 2 000 μ At 3 000 μ a unit discharge was encountered which responded to stimulations both of the contralateral MVN and IVN and superimposed on the slow negative wave With the IVN stimulation the slow positive wave in surface record was reversed to the slow negative one at a depth between 2 000 and 3 000 μ. Comparing each of the potential depth profiles evoked by stimulations of three vestibular nuclei the LVN stimulation caused a phase reversal of the surface negative between 1 200 and 1 600 μ and the MVN stimulation provoked the positive wave at the same depth, while the IVN stimulation produced only gradual increase in the amplitude of surface positive wave to 2 000 μ. These evidences suggested that the cortical depth projections of the LVN and the MVN resembled each other while those of the IVN were relatively different. The fact that any of the three contralateral

nuclei stimulations could make discharge to the same unit might reflect a possible convergence on the same unit from each of these nuclei.

3. *Unit Responses to Vestibular Nuclei Stimulation*

Recording of unit discharges by means of microelectrode was accomplished by five penetrations in four cats. Eleven units were responsive to vestibular stimulation, four responded to all vestibular nuclei stimulations (bilateral LVN, contralateral MVN, contralateral IVN), three units to only contralateral LVN, two units to three contralateral vestibular nuclei, one unit to the contralateral MVN, and one unit to the ipsilateral LVN. During penetration, unresponsive units to the vestibular nuclei stimulation were encountered more than twice as often as the responsive units. As shown in Fig. 5, the responsive unit to all vestibular nuclei stimulations always fired on the negative wave of field potential, having latencies of 2.5 msec, 3.7 msec, 3.3 msec and 2.4 msec for stimulation of the contralateral LVN, MVN, IVN and ipsilateral LVN respectively in the first spikes. Patterns of these responding discharges were illustrated as poststimulus-time histograms (PSTH) constructed with 50 successive stimuli (Fig. 6A–D). The PSTH of the contralateral LVN had an initial peak at 4–5 msec after stimulus artifact, followed by a longlasting inhibitory phase of about 40 msec. In contrast, with the ipsilateral LVN stimulation, the PSTH was characterized by a facilitatory response, with only a very short (about 6 msec) inhibition. This fact suggests that contralateral and ipsilateral LVN had an antagonistic relationship in regard to the cortical vestibular unit. Response pattern to the stimulation of the contralateral MVN was very similar to that of LVN stimulation. With the contralateral IVN stimulation, the inhibitory phase following initial excitation was not obvious.

4. *Effects of Visual Pathway Stimulation*

The LGNd stimulation elicited spike discharges corresponding with the positive and following

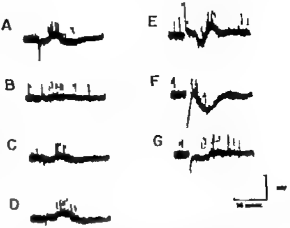

Fig. 5. An example of unitary response in the cortical vestibular field. A, C and D: contralateral LVN, MVN and IVN stimulation. B, E–G: ipsilateral LVN, LGNd, Clare-Bishop area and striate cortex stimulation respectively. All records are obtained from the same unit. Dots indicate the stimulus artifact.

negative deflections of the field potential (Fig. 5F). The latencies of spike discharges were divided into two groups, 5.2 msec and 8.0 msec. Even with the former latency, it was too long to postulate a direct connection between the LGNd and cortical vestibular field. There would seem to be some relay stations between them.

Visual cortex (VC) stimulation did not elicit a distinct response (Fig. 5G) with the vestibular units examined. In the PSTH, the VC stimulation showed a slight increase of discharges at 8 to 12 msec after the stimulation. However existing only in the frequency range of spontaneous discharges, it could not definitely be attributed to VC stimulation.

5. *Effects of Visual Association Area Stimulation*

Of the eleven units responsive to the vestibular nuclei stimulations, six were also fired by the C–B stimulation. The spike discharges superimposed on the negative wave of the field potential, and had a latency varying from 1.7 msec to 5 msec, averaging 2.76 ± 0.87 msec (mean and S.D.), as shown in Figs. 5F and 7G. In some units the initial excitation was composed of two stages which had latencies of 3.1 and 6.8 msec respectively (Fig. 7G). The excitation was

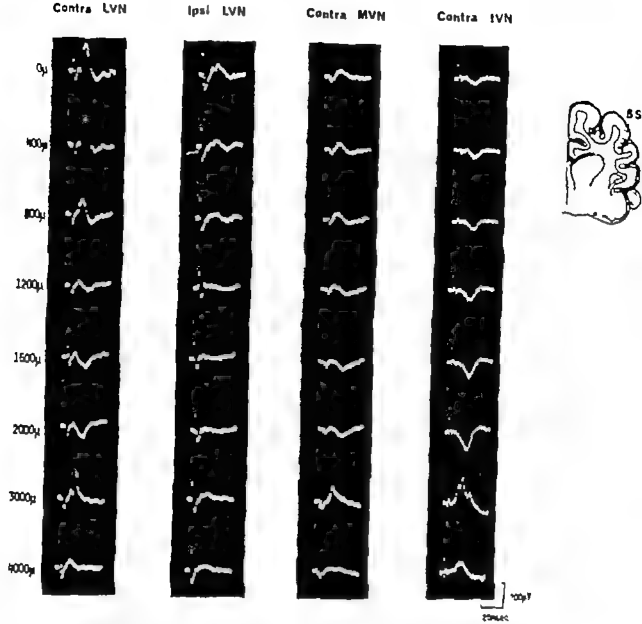

Fig 4 Depth analysis of cortical responses to electrical stimulation of the vestibular nuclei. *Orientation of the* electrode track is shown in drawing at right of figure. Note that the track passes into the neighbouring gyrus. Horizontal bars drawn in the track show intervals of mm.

latency of 17 msec appeared Amplitude increased with advance of the electrode With the IVN stimulation, a monophasic slow positive wave was elicited and its amplitude was increased to the depth of 2 000 μ At 3 000 μ a unit discharge was encountered which responded to stimulations both of the contralateral MVN and IVN and superimposed on the slow negative wave With the IVN stimulation, the slow positive wave in surface record was reversed to the slow negative one at a depth between 2 000 and 3 000 μ. Comparing each of the potential depth profiles evoked by stimulations of three vestibular nuclei the LVN stimulation caused phase reversal of the surface negative between 1 200 and 1 600 μ and the MVN stimulation provoked the positive wave at the same depth while the IVN stimulation produced only gradual increase in the amplitude of surface positive wave to 2 000 μ. These evidences suggested that the cortical depth projections of the LVN and the MVN resembled each other while those of the IVN were relatively different The fact that any of the three contralateral

nuclei stimulations could make discharge to the same unit that might reflect a possible convergence on the same unit from each of these nuclei.

3. *Unit Responses to Vestibular Nuclei Stimulation*

Recording of unit discharges by means of microelectrode was accomplished by five penetrations in four cats. Eleven units were responsive to vestibular stimulation: four responded to all vestibular nuclei stimulations (bilateral LVN, contralateral MVN, contralateral IVN), three units to only contralateral LVN, two units to three contralateral vestibular nuclei, one unit to the contralateral MVN, and one unit to the ipsilateral LVN. During penetration, unresponsive units to the vestibular nuclei stimulation were encountered more than twice as often as the responsive units. As shown in Fig. 5, the response unit to all vestibular nuclei stimulations always fired on the negative wave of field potential, having latencies of 2.5 msec, 3.7 msec, 3.3 msec and 2.4 msec for stimulation of the contralateral LVN, MVN, IVN and ipsilateral LVN respectively in the first spikes. Patterns of these responding discharges were illustrated as poststimulus-time histograms (PSTH) constructed with 50 successive stimuli (Fig. 6A–D). The PSTH of the contralateral LVN had an initial peak at 4–5 msec after stimulus artifact, followed by a longlasting inhibitory phase of about 40 msec. In contrast, with the ipsilateral LVN stimulation, the PSTH was characterized by a facilitatory response, with only a very short (about 6 msec) inhibition. This fact suggests that contralateral and ipsilateral LVN had an antagonistic relationship in regard to the cortical vestibular unit. Response pattern to the stimulation of the contralateral MVN was very similar to that of LVN stimulation. With the contralateral IVN stimulation, the inhibitory phase following initial excitation was not obvious.

4. *Effects of Visual Pathway Stimulation*

The LGNd stimulation elicited spike discharges corresponding with the positive and following

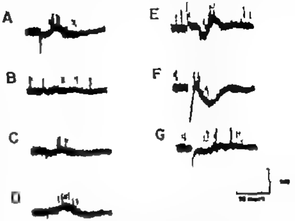

Fig. 5. An example of unitary response in the cortical vestibular field. A, C and D: contralateral LVN, MVN and IVN stimulation. B, E–G: ipsilateral LVN, LGNd, Clare-Bishop area and striate cortex stimulation respectively. All records are obtained from the same unit. Dots indicate the stimulus artifact.

negative deflections of the field potential (Fig. 5E). The latencies of spike discharges were divided into two groups, 5.2 msec and 8.0 msec. Even with the former latency, it was too long to postulate a direct connection between the LGNd and cortical vestibular field. There would seem to be some relay stations between them.

Visual cortex (VC) stimulation did not elicit a distinct response (Fig. 5G) with the vestibular units examined. In the PSTH, the VC stimulation showed a slight increase of discharges at 8 to 12 msec after the stimulation. However, existing only in the frequency range of spontaneous discharges, it could not definitely be attributed to VC stimulation.

5. *Effects of Visual Association Area Stimulation*

Of the eleven units responsive to the vestibular nuclei stimulations, six were also fired by the C–B stimulation. The spike discharges superimposed on the negative wave of the field potential, and had a latency varying from 1.7 msec to 5 msec, averaging 2.76±0.87 msec (mean and S.D.), as shown in Figs. 5F and 7G. In some units the initial excitation was composed of two stages which had latencies of 3.1 and 6.8 msec respectively (Fig. 7G). The excitation was

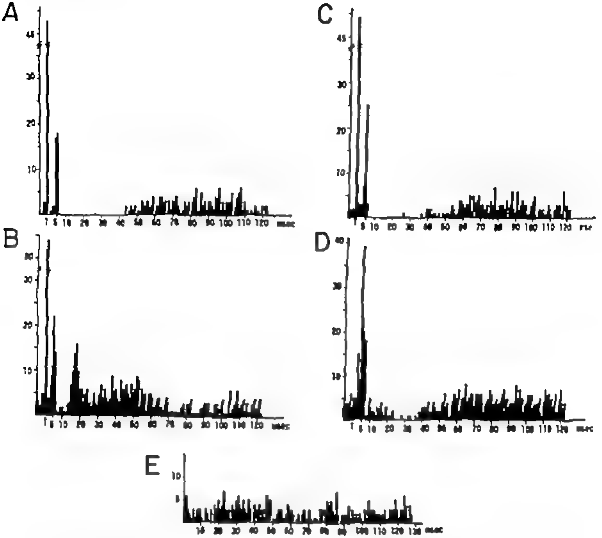

Fig 6 Post-stimulus time histogram for a unit in the vestibular cortical field responded to the electrical stimulation of vestibular nuclei. followed by a long-lasting inhibitory phase of more than 100 msec, and then a facilitatory phase or the rebound phenomena, which reached maximum at 150 msec after stimulation (Fig 7F and Fig. 8A, B) Concerning the long lasting inhibitory phase an interaction between the vestibular and the Clare–Bishop stimulations was examined, using the C–B stimulation for a conditioning shock and the contralateral LVN stimulation for a test shock. During the initial excitatory phase of about 20 msec elicited by the conditioning shock the field potential evoked by the test shock increased its amplitude up to 110% of control and the spike discharge was lasted until 25 msec. Thereafter the amplitude of field potentials evoked by the test shock decreased immediately to reach minimum at about 40 to 50 msec. The decrease in amplitude lasted about 120 msec, during which no spike discharge was elicited (Fig. 7 and Fig. 8A B).

DISCUSSION

1 *Location of cortical vestibular center*

One purpose of the present study was to resolve whether any difference exists in the projection from each of the three vestibular nuclei because Andersson & Gernandt (1954) had reported that the cortical projections from the particular end organs were revealed separate distributions

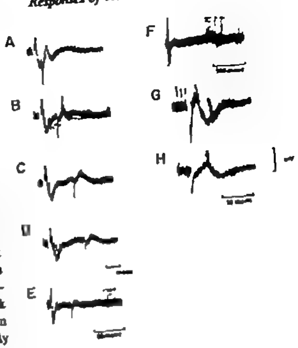

Fig. 7. Interaction between contralateral LVN and ipsilateral Clare-Bishop area stimulations. A–D: conditioning and test shocks were applied in the Clare-Bishop area and the contralateral LVN, respectively. Note the difference in time scales. F–H, control records of the responses of the same unit to the stimulation of the contralateral LVN (H), the ipsilateral Clare-Bishop area (F and G).

moreover the vestibular nerve fibers originating from each end organ were found to terminate in different vestibular nuclei (Gacek, 1969). Another aim was to confirm the extent of projection fields of the vestibular nuclei. As for the difference in projection field, there was only a slight difference with MVN and IVN but both fields were actually within that of LVN. This corroborated the data presented by Andersson & Gernandt (1954), namely that the projection field of the MVN was situated caudo-medially

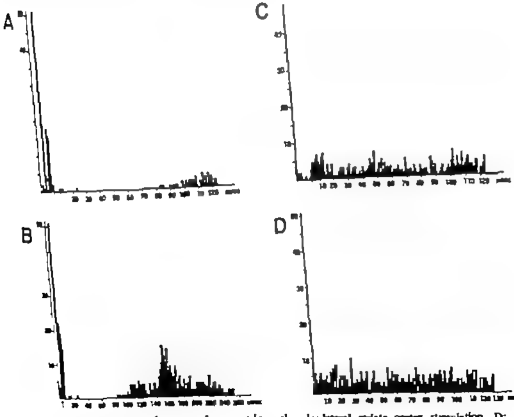

Fig. 8. Post-stimulus time histogram for unit in vestibular field. A and B, Clare-Bishop area stimulation, C: ipsilateral striate cortex stimulation, D: spontaneous firing. All else as in Fig. 6.

to that of the IVN The whole extent of the cortical projection fields was consistent with the experiments involving stimulation of vestibular nerves performed by Walzl & Mountcastle (1949) Kempinsky (1951) and Mickle & Ades (1952) but findings did not agree strictly with data from stimulation of the vestibular nuclei by Massopust & Daigle (1960) which showed more ventro-caudal spreading of the fields than in the present study This latter disagreement may owe to the difference in stimulating sites as well as differing depth of anesthesia.

Concerning a dominancy of responses to either side of the vestibular nuclei most papers have indicated that the projection fields responding were principally contralateral while the extent of the fields projecting from each side were symmetrical In our experiments, this was verified except for stimulation of LVN The main area of response to the ipsilateral LVN stimulation was smaller than with the contralateral one and it inclined slightly toward the lateral part Some units on the other hand exhibited an antagonistic relationship they were facilitated by the ipsilateral LVN stimulation but inhibited by contralateral stimulation throughout the same period This suggests that the region may play a part in motor control acting as an oculomotor for example None the less, to read Kornhuber (1972) the primary vestibular projection area of the cortex does not belong to the oculomotor field as revealed by stimulation experiments Against this, our previous experiments (Miyake et al 1973) have suggested that this region also is somehow involved with eye-movements, its electrical stimulation having revealed conjugate centering. Pasik et al (1971) argued that the efferent pathways responsible for the fast phase of optokinetic nystagmus are the same as those for conjugate gaze Wood et al (1973) also pointed out that in order to impair the cortical optokinetic nystagmus cortical lesions have to involve not only the visual cortex but the wide region of the association area including the suprasylvian sulcus belt as well as the vestibular center From these further evidences, the cortical vestibular fields may also be considered to have a role in the visual regulation of eye position, as described by Kornhuber (1972)

2. *Bimodal projection in vestibular center*

According to Sanides & Hoffmann (1968), the vestibular projection area is situated in the anterior suprasylvian sulcus belt S_{aa}, and a part of the suprasylvian fringe area, SSF which is located in the suprasylvian integration belt, SSI Therefore various somatosensory auditory and visual information comes to the adjacent areas. Moreover as found by Oscarsson & Rosen (1963) and Fredrickson (1964) in the cat, and by Fredrickson et al (1966*a*) Fredrickson et al (1966*b*) and Schwarz et al (1973) in the monkey Group I muscle afferents and deep somatic afferents terminate in the vestibular field, which manifested a bimodal projection having two kinds of proprioception These two kinds of proprioception were seen to converge not only on the cortical level but also on the level of the vestibular nuclei accordingly the vestibular nuclei play a role of postural and oculomotor regulation as the lower order reflex center From the fact that the vestibular nuclei receive a bimodal sensation the question arises, as to whether the projection field responding to vestibular nuclei stimulation coincides with that of vestibular nerve stimulation or whether this field might extend over the somatosensory area. In the present experiments, mainly responding areas to vestibular nuclei stimulation were almost consistent with those responsive to vestibular nerve stimulation This fact may suggest that the cortical vestibular center possibly receives information principally vestibular in nature.

3 *Visuo-vestibular interaction*

The suprasylvian sulcus belt, which is very proximate to the vestibular cortex functions as a visual association cortex according to Clare & Bishop (1954) The C–B area was found to receive direct projection fibers mainly from the border region between areas 17 and 18, upon examination of the retinotopic organization (Shoumura, 1972 Shoumura & Itoh, 1972) moreover it connects profusely with the AMSS where exist

the gating mechanisms as reported by Dow & Dubner (1971). However the cortico-cortical projection of the vestibular fields is not yet clear. In present experiments, applying electrical stimulation to the anterior portion of the C–B area, of 11 units which responded to the vestibular stimulation, [illegible] reacted to the C–B stimulation. The latency of spike discharges was about 1.67 msec. If a conduction velocity is estimated as about 10 m/sec for the connecting path between the C–B area and the vestibular field, the latency is shorter enough to indicate a monosynaptic connection. Although there are the thalamo-cortical projections to the vestibular field arising from PO group, medial geniculate nucleus, pulvinar (Jones & Leavitt, 1973), and VPL (Mickle & Ades, 1954 Sans & Marty 1971), a cortico–thalamo–cortical projection may be too long to account for such a short latency of 1.67 msec. On the other hand, the stimulation of the visual cortex elicited little or no response from the vestibular field neurons. On this fact it can be considered that a focal stimulation may not produce an obvious response, provided that projection fibers did not connect directly or they terminated only sparsely

By the LGNd stimulation, 6 units discharged with latencies of 5.2 and [illegible].0 msec. Such 6 units were composed of 1 unit responding only with the LGNd stimulation, 1 unit discharging both with LGNd and LVN stimulations, and 3 units with LVN, MVN IVN, C B and LGNd stimulations. Thus, half of the 6 units responsive to LGNd stimulation could also be activated with C B stimulation. This finding suggests that a pathway from the LGNd may not necessarily pass through the portion of the C B area stimulation, and points to the C B area as one very probable pathway from the LGNd.

Neuronal responses of the cortical vestibular center to the C B stimulation consisted of an initial excitation of 20 msec followed by a long-lasting inhibition as long as 120 msec. This sequence of excitation-inhibition may practise just as gate for selection of input to the vestibular center, namely visual information, which may probably be processed at the visual association area and then relayed to the vestibular center There it serves to control the vestibular and somatosensory information to execute higher regulation of postural and oculomotor functions.

A QUANTITATIVE TEST OF OPTOKINETIC NYSTAGMUS AND ITS DATA PROCESSING BY COMPUTER

Takashi Tokita, Tomoo Suzuki, Takaya Hibi and Tasuku Tomita

From the Department of Otolaryngology, Gifu Medical School, Gifu, Japan

Abstract. A quantitative test of optokinetic nystagmus was proposed. Horizontal nystagmus was examined by a large rotating cylinder with vertical stripes. Nystagmus responding to the cylinder rotation with an acceleration of 2°/sec² for 90 seconds was recorded with an electronystagmograph. On the records, the number of beats, average eye-speed, and average amplitude per each 10 seconds were calculated. This method was suitable for testing the nature of optokinetic nystagmus which indicates the ability of the eyes to adapt to objects moving through the visual field. Moreover, in order to save trouble in hand-scoring of each parameter of nystagmus, computer processing of electronystagmographic data was introduced. The results were printed numerically on the teletypewriter and displayed graphically on a cathode ray tube and X–Y recorder. By displaying measured values on the form already printed with the normal ranges, the evaluation of the results was performed rapidly and objectively.

Since Bárány (1921) first introduced it into the clinical examination of hemianopsia, optokinetic nystagmus has been observed in cases with disturbance of the visual organ, labyrinth, cerebrum, cerebellum, and brain-stem by Fox & Holmes (1926), Cogan & Loeb (1949), Carmichael et al. (1954), Sato (1955), Enoksson (1956), Smith & Cogan (1959, 1960), and Smith (1963). The results of these tests were evaluated on the basis of the number of nystagmus beats, the eye-speed in the slow phase of nystagmus, amplitude, and differentiated response between right and left nystagmus. However, the evaluation of these tests has remained rather qualitative, and its quantitative evaluation is yet to be established.

Optokinetic nystagmus is an equilibrium reflex to stabilize the position of retinal images of successive objects passing through the visual field in order to obtain clear vision. Grüttner (1939), Mackensen (1954), Mackensen & Wiegmann (1959), Koike (1959), Mackensen & Uber (1960), Mackensen & Schumacher (1960), Mackensen et al. (1961), Honrubia et al. (1967), Honrubia et al. (1968), and Komatsuzaki et al. (1969), clearly described the nature of optokinetic nystagmus. The tests of optokinetic nystagmus should be performed taking account of its physiological function. Namely, the nystagmus should be observed in relation to optokinetic stimulation, and the character of nystagmus should be demonstrated in various parameters such as the number of nystagmus beats, the eye-speed of slow and rapid phase, and the amplitude. These results should then be evaluated objectively.

The purpose of the present paper is to describe (1) a method for a quantitative test of optokinetic nystagmus developed by the present authors, (2) its normal ranges, and (3) data processing by the PDP 12 computer.

METHOD

1. *Apparatus*

(1) For examination of horizontal optokinetic nystagmus, a large cylinder made of a white vinyl curtain was used. The cylinder was 2 m in diameter and 2 m in height. Along the inner surface of the cylinder, 12 vertical black stripes were drawn 5 cm in width at equal distances. A subject was placed on a chair located in the center of the cylinder with his head held in position. The

A QUANTITATIVE TEST OF OPTOKINETIC NYSTAGMUS AND ITS DATA PROCESSING BY COMPUTER

Takeshi Tokita, Tomoo Suzuki, Takaya Hibi and Tasuku Tomita

From the Department of Otolaryngology, Gifu Medical School, Gifu, Japan

Abstract. A quantitative test of optokinetic nystagmus was proposed. Horizontal nystagmus was examined by a large rotating cylinder with vertical stripes. Nystagmus responding to the cylinder rotation with an acceleration of 2°/sec² for 90 seconds was recorded with an electronystagmograph. On the records, the number of beats, average eye-speed, and average amplitude per each 10 seconds were calculated. This method was suitable for testing the nature of optokinetic nystagmus, which indicates the ability of the eyes to adapt to objects moving through the visual field. Moreover, in order to avoid trouble in hand-scoring of each parameter of nystagmus, computer processing of electronystagmographic data was introduced. The results are printed numerically on the teletypewriter, and displayed graphically on a cathode ray tube and X-Y recorder. By displaying measured values on the form already printed with the normal ranges, the evaluation of the results was performed readily and objectively.

Since Bárány (1921) first introduced it into the clinical examination of hemianopsia, optokinetic nystagmus has been observed in cases with disturbance of the visual organ, labyrinth, cerebrum, cerebellum, and brain-stem by Fox & Holmes (1926), Cogan & Loeb (1949), Carmichael et al. (1954), Sato (1955), Enoksson (1956), Smith & Cogan (1959, 1960), and Smith (1963). The results of these tests were evaluated on the basis of the number of nystagmus beats, the eye-speed in the slow phase of nystagmus, amplitude, and differentiated response between right and left nystagmus. However, the evaluation of these tests has remained rather qualitative, and its quantitative evaluation is yet to be established.

Optokinetic nystagmus is an equilibrium reflex to stabilize the position of retinal images of successive objects passing through the visual field in order to obtain clear vision. Grüttner (1939), Mackensen (1954), Mackensen & Wiegmann (1959), Koike (1959), Mackensen & Uber (1960), Mackensen & Schumacher (1960), Mackensen et al. (1961), Honrubia et al. (1967), Honrubia et al. (1968), and Komatsuzaki et al. (1969), clearly described the nature of optokinetic nystagmus. The tests of optokinetic nystagmus should be performed taking account of its physiological function. Namely, the nystagmus should be observed in relation to optokinetic stimulation, and the character of nystagmus should be demonstrated in various parameters such as the number of nystagmus beats, the eye-speed of slow and rapid phase, and the amplitude. These results should then be evaluated objectively.

The purpose of the present paper is to describe (1) a method for a quantitative test of optokinetic nystagmus developed by the present authors, (2) its normal ranges, and (3) data processing by the PDP 12 computer.

METHOD

1. *Apparatus*

(1) For examination of horizontal optokinetic nystagmus, a large cylinder made of a white vinyl curtain was used. The cylinder was 2 m in diameter and 2 m in height. Along the inner surface of the cylinder, 12 vertical black stripes were drawn 5 cm in width at equal distances. A subject was placed on a chair located in the center of the cylinder with his head held in position. The

examination was carried out for both right and left rotation of the cylinder

(2) For examination of vertical optokinetic nystagmus, a Jung type projection device was used The radius of the projection screen was 90 cm and the visual angles were 180 vertically and 60 horizontally The interval of light stripes was 30 and the width of the stripes was 3 cm A subject was seated 90 cm away from the screen with his head positioned at the center of the circle made by the screen, and upward and downward optokinetic stimuli were given

2. *Optokinetic stimulation*

(1) Examination of horizontal optokinetic nystagmus. The cylinder was rotated electrically with an angular acceleration of 2°/sec² for 90 seconds. The cylinder speed was gradually increased from 0 to 180 /sec.

(2) Examination of vertical optokinetic nystagmus. The light stripes were rotated with an angular acceleration of 1 /sec² for 90 seconds. The final rotation speed was 90°/sec.

The accelerated optokinetic stimulation was adopted to check visual adaptation to moving objects. To standardize recognition of stripes, subjects were instructed to count the stripes moving by

3 *Recording*

The nystagmus was recorded with an electronystagmograph (ENG) A ten-degree eye movement was calibrated to be equivalent to 1 cm of pen deflection of the recorder The paper speed was 1 cm/sec Time constant was set at 1 5 seconds. For the observation of the beating field of nystagmus a DC amplifier was used

4 *Parameter and measurements of optokinetic nystagmus*

The following measurements were made from the electronystagmogram.

(i) The total number of nystagmus beats for 90 seconds

Furthermore, the ENG recording for 90 seconds was divided into 9 equal parts at 10 second intervals and the following measurements were performed

(ii) The number of nystagmus beats for each 10 seconds

(iii) The average eye-speed of slow phase of nystagmus for each 10 seconds.

(iv) The average amplitude for each 10 seconds.

(v) The amplitude histogram for each 10 seconds.

The reason for calculating the average values for each 10 seconds was to observe how the occurrence of nystagmus changed with the increase of the speed of cylinder rotation The values measured from ENG record of each clinical case were plotted in each figure, the abscissa showing the time course and the ordinate indicating the number of nystagmus beats, the eye-speed of slow phase, or the amplitude. Use of figures on which the below mentioned normal ranges had already been printed, facilitated immediate evaluation of the results.

(vi) The beating field of nystagmus. The distance between the middle point of the slow phase of each nystagmus and the base line was measured on the ENG recording and the values were plotted on graph paper

NORMAL RANGES

1 *Subjects*

To determine the normal ranges, examinations were made upon two groups composed of 15 male and female subjects respectively and ranging in age from fifteen to fifty

2. *Calculation of normal ranges*

With horizontal optokinetic nystagmus, nystagmus induced by right rotation of the cylinder (left nystagmus) and nystagmus induced by left rotation of the cylinder (right nystagmus) were processed together From the measured values of 30 cases (60 sides) 95 confidence limits and rejection limits at the 5% of level of significance of the number of beats, the eye-speed of slow component and the amplitude were calculated. In the amplitude histogram the average values were calculated The beating field of nystagmus

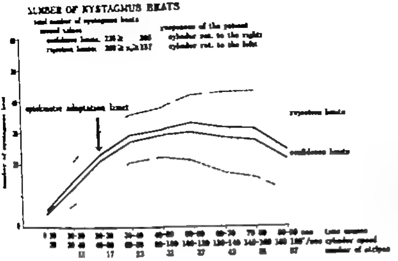

Fig. 1. Normal ranges in the number of beats of the horizontal optokinetic nystagmus induced by cylinder rotation with angular acceleration of 1°/sec² for 90 seconds.

was estimated from the graphs in which measured values were plotted.

For vertical optokinetic nystagmus, since the accurate calibration of the amplitude of eye movement was often difficult, only the normal ranges in the number of nystagmus beats were calculated. Values for nystagmus induced by upward stripe rotation (downward nystagmus) and those for downward stripe rotation (upward nystagmus) were calculated separately.

3. *Normal ranges of horizontal nystagmus*

(1) The total number of nystagmus beats in 90 seconds.

95% confidence limit $220 \geq m \geq 206$

rejection limit (level of significance = 5%) $269 \geq x_0 \geq 157$

(2) The number of nystagmus beats for each 10 seconds. Fig. 1 shows confidence limits and rejection limits for each 10 seconds. The number of beats increases proportionally with the speed of cylinder rotation up to 40–60°/sec. But as cylinder speed increases beyond this range, the increase in the number of beats is proportionately less, and the number of beats actually decreases when the cylinder speed exceeds 100°–120°/sec. The upper limit of the linear increase in

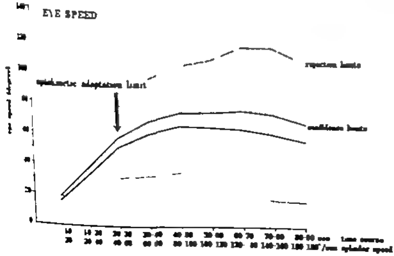

Fig. 2. Normal ranges in the eye-speed of slow phase of the horizontal optokinetic nystagmus.

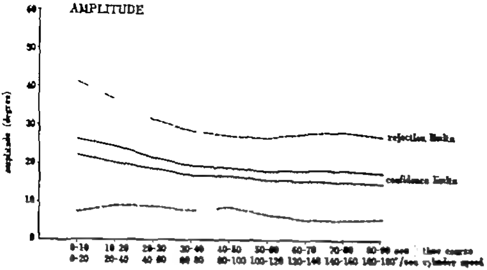

Fig 3 Normal ranges in the amplitude of the horizontal optokinetic nystagmus.

beats (indicated with an arrow) is the limit of visual fixation to objects passing through the visual field (optokinetic adaptation limit)

(3) The average eye-speed of slow phase of nystagmus for each 10 seconds Fig. 2 shows the confidence and rejection limits for average eye speed of slow phase in nystagmus for each 10 seconds. The speed of cylinder rotation and the eye-speed are the same until the cylinder speed reaches up to 40 –60°/sec. But as cylinder speed increases beyond this range the increase in the eye-speed is proportionately less. The upper limit where the cylinder speed and the eye-speed are still the same (indicated with an arrow in the figure) is the optokinetic adaptation limit.

(4) The average amplitude for each 10 seconds. The confidence limits and rejection limits of the average amplitude for each 10 seconds are shown in Fig. 3 As the speed of cylinder rota tion increases, the amplitude becomes smaller

(5) The amplitude histogram for each 10 seconds. Fig. 4 shows the histogram of amplitude in each interval of 10 seconds. When the speed of cylinder rotation remained low nystagmic amplitudes were observed in all the ranges of 0°–10° 10°–20° 20 –30 and over 30° As the rotation speed increased, the amplitude in the range of 20 –30° became more frequent, and that of 10 –20° became more pronounced in much higher cylinder speeds.

(6) The beating field of nystagmus. Fig. 5 indicates the beating field of nystagmus in a

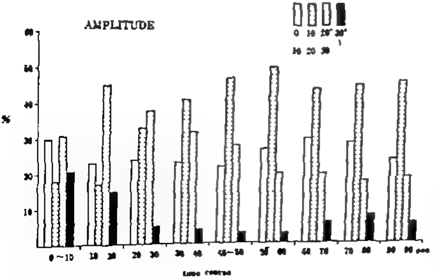

Fig 4 Amplitude histogram of the horizontal optokinetic nystagmus (mean values).

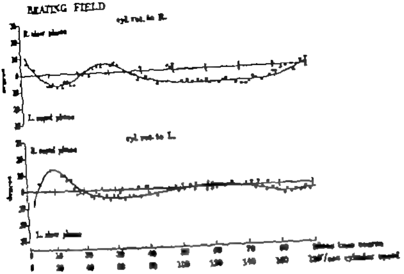

Fig. 5. Beating field of the horizontal optokinetic nystagmus in normal subject.

normal subject. Although at the onset of stimulation the beating field is found on the side of the slow phase, as the stimulation continues it immediately shifts to that of the rapid phase. When the speed of cylinder rotation exceeds 40°/sec, it shifts back to the slow phase side and then it stays near the base line despite the further increase of stimulation. This shifting pattern of the beating field is most commonly observed among normal subjects.

4. *Normal ranges of vertical nystagmus*

(1) The total number of nystagmus beats in 90 seconds.

Downward rotation (upward nystagmus)

95 confidence limit $152 \geq m \geq 129$

rejection limit (level of significance = 5 %)

$204 \geq x_0 \geq 76$

Upward rotation (downward nystagmus)

95 % confidence limit $140 \geq m \geq 1\ 4$

rejection limit (level of significance = 5 %)

$179 \geq x_0 \geq 85$

(2) The number of nystagmus beats per 10 seconds. In vertical nystagmus, both upward and downward nystagmus show less increase in the number of beats when the speed of light stripes 20°/sec. The result demonstrates that the optokinetic adaptation limit for vertical optokinetic stimuli is less than for horizontal optokinetic stimuli.

DATA PROCESSING BY COMPUTER

1. *Equipment*

The optokinetic nystagmus was recorded on a magnetic tape together with recording by a pen oscillograph using an electronystagmograph. The nystagmographic data were analyzed with a PDP 12 computer (DEC) consisting of a central processing unit (4096 word core memory), analog to digital converter LINC tape system, cathode ray tube display system, teletype unit, and X–Y recorder. The following computer program, OKNYST has been developed for the data processing in a quantitative test of optokinetic nystagmus.

2. *Program (OKNYST)*

The program was written in an assembly language (LINC and 8 mode instructions). The autoprocessing of nystagmographic data was performed as follows

(1) Chart number name, sex, age, date, direction of cylinder rotation, sampling interval, and average time were asked on the teletypewriter

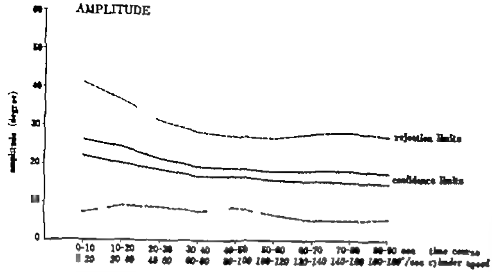

Fig 3. Normal ranges in the amplitude of the horizontal optokinetic nystagmus.

beats (indicated with an arrow) is the limit of visual fixation to objects passing through the visual field (optokinetic adaptation limit)

(3) The average eye-speed of slow phase of nystagmus for each 10 seconds Fig. 2 shows the confidence and rejection limits for average eye speed of slow phase in nystagmus for each 10 seconds. The speed of cylinder rotation and the eye-speed are the same until the cylinder speed reaches up to 40 –60 /sec. But as cylinder speed increases beyond this range the increase in the eye-speed is proportionately less The upper limit where the cylinder speed and the eye-speed are still the same (indicated with an arrow in the figure) is the optokinetic adaptation limit

(4) The average amplitude for each 10 seconds. The confidence limits and rejection limits of the average amplitude for each 10 seconds are shown in Fig. 3 As the speed of cylinder rotation increases, the amplitude becomes smaller

(5) The amplitude histogram for each 10 seconds. Fig. 4 shows the histogram of amplitude in each interval of 10 seconds. When the speed of cylinder rotation remained low nystagmic amplitudes were observed in all the ranges of 0 –10 10°–20° 20°–30 and over 30° As the rotation speed increased, the amplitude in the range of 20 –30° became more frequent, and that of 10 –20 became more pronounced in much higher cylinder speeds.

(6) *The beating field of nystagmus.* Fig. 5 indicates the beating field of nystagmus in a

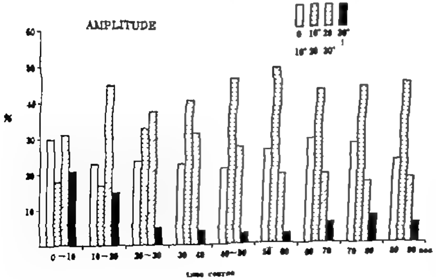

Fig 4 Amplitude histogram of the horizontal optokinetic nystagmus (mean values).

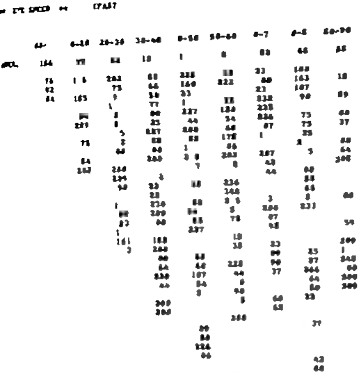

Fig 7 Teletypewriter printout of the eye-speed of rapid phase of the horizontal optokinetic nystagmus in a normal subject.

low and rapid phases, etc. could be printed on the teletypewriter

Results

The optokinetic nystagmus of 30 normal subjects was measured using the PDP 12 computer With the measured values, 95% confidence limits and rejection limits at 5% of level of significance were calculated for number of beats, eye-speed, and amplitude. When these results were compared with those obtained from hand scoring, the confidence and rejection limits had narrower ranges This was probably due to the small dispersion of measured values.

DISCUSSION

1 *Significance of the examination of optokinetic nystagmus*

(i) The physiological function of nystagmus is to stabilize the position of retinal images of objects moving through the visual field in order to obtain clear vision. Therefore, optokinetic nystagmus is an equilibrium reflex of the eyes and its examination tests the primary function of nystagmus. On the other hand, the examination of induced labyrinthine nystagmus is a test of nystagmus without the function maintaining visual fixation to the moving objects. In the examination of nystagmus, the test of both kinds of nystagmus, which differ in their physiological significance, is useful to explain the peculiar characteristics of nystagmic abnormalities.

(ii) Optokinetic nystagmus is a reflex mediated through the retina, superior colliculus, lateral geniculate body striate cortex, brain-stem, and oculomotor nuclei. This reflex is modified by the cerebrum, cerebellum, basal ganglia, and reticular formation of the brain-stem. Therefore the examination of optokinetic nystagmus is effective to check any central vertigo and equilibrium disturbance.

(iii) Since the appearance of optokinetic nystagmus indicates the ability of the eyes to adapt to objects moving through the visual

and total eyeball velocity over any selected number of seconds and an analog display of the eye position and velocity on a cathode ray tube. Herbert et al. (1968), using a Swedish Datasaab D21 computer with programs coded in Algol, presented (*a*) differentiated response under correction for spontaneous nystagmus, (*b*) total amplitude, (*c*) total number of beats within different phases of the recording, (*d*) duration of each phase, (*e*) occurrence in time of maximum response and its size, and (*f*) maximum frequency in caloric nystagmus. The results were printed numerically and the differentiated responses were graphically displayed on a line printer. Tole and Young (1971) used hybrid equipment consisting of a Digital Equipment PDP-8 digital computer connected to a GSP 290T analog computer and calculated cumulative slow phase position and slow phase velocity in vestibular nystagmus and optokinetic nystagmus. Matz et al. (1970) calculated the number of nystagmus beats and the total eye displacement in the rapid phase of caloric nystagmus for every 5 seconds with an analog computer and printed them on an X–Y plotter.

In performing the quantitative test of optokinetic nystagmus, using a PDP 12 computer with a program (OKNYST coded in assembly language), the authors calculated the number of beats, eye-speed of slow and rapid phase, and amplitude. This procedure offered the following advantages. (i) Computer analysis slashed the time usually necessary for manually performing the measurements and processing of nystagmus. (ii) By numerically printing out the measured values on the teletypewriter and displaying them on the cathode ray tube and X–Y recorder the evaluation of the results was done readily and objectively.

However problems in the recognition of abnormal wave forms, and auto-diagnosis remain to be solved.

field *the superior eye function of a ball player* or the disturbance of visual fixation function of a drunken person may be demonstrated objectively by the examination of optokinetic nystagmus.

2. *Merits of the quantitative test of optokinetic nystagmus*

(i) By using the cylinder rotation with angular acceleration of 1 /sec^2 for 90 seconds as optokinetic stimulation, it is possible to continuously observe visual adaptation to moving objects (stripes) with gradually increased speed from 0 to 180 /sec. Especially the optokinetic adaptation limit can be observed

(ii) By quantitative comparison of the values obtained by testing clinical cases with the normal ranges, the results are evaluated easily and objectively

(iii) Since the number of beats, eye-speed, and amplitude of optokinetic nystagmus are examined, the degree and character of nystagmic abnormality can be better demonstrated.

Despite the fact that the quantitative test described above has many merits, it requires time-consuming work, which is why the computer processing of nystagmographic data has been developed.

3 *Computer processing of nystagmographic data*

Using a specially designed computer Johnson et al. (1967) presented a digital readout of the average eyeball velocity of the preceding second

OPTIC ORGAN AND CERVICAL PROPRIOCEPTORS IN MAINTENANCE OF BODY EQUILIBRIUM

Manabu Hinoki, Sonoji Hine, Shuji Okada, Yoshio Ishida, Satoshi Koike and Shunichi Shizuku

From the Department of Otolaryngology, School of Medicine, Tokushima University, Tokushima, Japan

Abstract. Two experiments were made on the functional correlation between the optic organ and the cervical proprioceptors in maintenance of body equilibrium. Experiment I. The effects of weak and strong electric stimulation of the deep nuchal muscles on changes in optokinetic nystagmus and optokinetic after-nystagmus were compared in adult non-albino rabbits with binocular vision. Experiment II. Experiment I was repeated on rabbits with monocular vision giving optokinetic stimulation moving from the side of the blindfolded eye to that of the open eye and applying only weak electric stimulation to the neck muscles. The results obtained were as follows: (1) Experiment I. Weak electric stimulation of the deep nuchal muscles of rabbits with binocular vision tended to promote optokinetic nystagmus with either no significant change or decrease in optokinetic after-nystagmus. Strong electric stimulation had the opposite effects, i.e. it tended to inhibit optokinetic nystagmus and activate optokinetic after-nystagmus. It also produced abnormal optokinetic nystagmus, such as the inversion phenomenon of optokinetic nystagmus and optokinetic nystagmus fixing. (2) Experiment II. Weak electric stimulation of the deep nuchal muscles of rabbits with monocular vision had similar effects to those in experiment I, but promotion of optokinetic nystagmus was less obvious, while activation of optokinetic after-nystagmus was more marked. In addition, the inversion phenomenon of optokinetic nystagmus developed even on weak electric stimulation. From these results the following conclusions were drawn. (1) The cervical proprioceptors can function as two mechanisms causing promotion and break down of equilibrium of the optokinetic system. (2) The cervical proprioceptors, as an organ of equilibrium, can exert two different actions on the optokinetic eye reflexes, i.e., they can promote optokinetic nystagmus and inhibit optokinetic after-nystagmus.

It is generally accepted that there is a close relationship between the optic organ and the labyrinth in maintenance of body equilibrium. For instance, Fukuda, Hinoki and Tokita found that when an adequate labyrinthine stimulus was given to rabbits at the same time as an optokinetic stimulus, the animals showed increased adaptability to optokinetic stimulation and responded well to environmental changes that were too rapid for reaction of the optic organ alone (Fukuda et al., 1957). It seems possible that there is a similar relationship between the optic organ and the cervical proprioceptors in maintenance of body equilibrium. For instance, Hinoki & Terayama reported that when procaine, which blocks the activity of gamma fibers and consequently inhibits the function of the proprioceptors, was injected into the deep nuchal muscles of guinea pigs, development of optokinetic head and eye nystagmus was strongly inhibited (Hinoki & Terayama, 1966). Furthermore, we found that optokinetic nystagmus was inactive in many vertigo cases with whiplash injury who complained of neck pain and showed abnormal EMG's from the neck region, and that when the neck of these patients was fixed with a collar optokinetic nystagmus developed actively in parallel with reduction in the abnormal EMG's (Hinoki et al., 1971).

To test the validity of this idea in more detail, it seems necessary to determine whether changes in optokinetic reflexes are parallel with the intensity of stimuli given to the cervical proprioceptors in man and animals. No systematic experimental studies have yet been made on this.

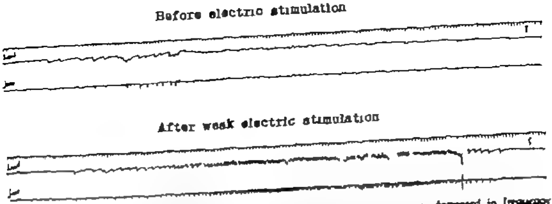

Fig. 1. Optokinetic nystagmus and optokinetic after-nystagmus before and after weak electric stimulation of the deep nuchal muscles of a rabbit with binocular vision. Before electric stimulation, optokinetic nystagmus developed fairly well while the velocity of cylinder rotation was low and optokinetic stimuli were enough for the optic organ. However when the velocity of cylinder rotation increased, this nystagmus decreased in frequency and amplitude. After weak electric stimulation, nystagmic responses increased appreciably so that the velocity of cylinder rotation giving the maximum frequency of nystagmus increased. No optokinetic after-nystagmus was seen before or after electric stimulation.

nystagmus before and after weak electric stimulation of the deep nuchal muscles of another rabbit with binocular vision. Before electric stimulation, optokinetic nystagmus of small or medium amplitude developed to the left, but it was inactive during optokinetic stimulation. Five jerks of optokinetic nystagmus were observed in 180 seconds. The velocity of cylinder rotation giving the maximum frequency of nystagmus was between 0° and 20°/sec. Optokinetic after-nystagmus of medium amplitude developed to the right and showed 7 jerks. The ENG at the bottom of this figure shows optokinetic nystagmus and optokinetic after nystagmus after electric stimulation. Again nystagmus increased appreciably optokinetic nystagmus to 27 jerks in 180 seconds and the velocity of cylinder rotation giving the maximum frequency of nystagmus to between 21 /sec and 40 /sec. One jerk of optokinetic after nystagmus was seen to the right.

2. *Results in other animals.* Table I shows results of weak electric stimulation of the neck muscles in 8 other rabbits. Electric stimulation increased the total number of nystagmic jerks in 6 of the 8 animals and raised the velocity of cylinder rotation giving the maximum frequency of nystagmus in all of these 6 animals. However it reduced the frequency of nystagmic jerks in 2 rabbits and in one of these it decreased the velocity of cylinder rotation giving the maximum frequency of nystagmus.

Results on changes in the relationship between optokinetic nystagmus and optokinetic after nystagmus caused by weak electric stimulation of the neck muscles were as follows. Six of the 8 rabbits showed increased optokinetic nystagmus, with and without decrease in optokinetic after nystagmus. Incidentally only 2 of these 6 rabbits showed optokinetic after-nystagmus before electric stimulation. Two of the 8 rabbits showed inhibition of optokinetic nystagmus with no sign of development of optokinetic after nystagmus. Moreover after weak electric stimulation, 3 rabbits showed abolition of the inversion phenomenon of optokinetic nystagmus in parallel with promotion of this nystagmus.

(b) *Strong electric stimulation of the neck muscles*

1. *Representative cases.* Rabbit No. 11. Fig. 3 shows recordings of optokinetic nystagmus and optokinetic after nystagmus before and after strong electric stimulation of the deep nuchal muscles of a rabbit with binocular vision. Be

EXPERIMENTAL

1 *Method of Electric Stimulation of the Neck Muscles*

We applied two kinds of electric stimuli one was 10 msec 10 Hz pulse waves, at 1 volt for 90 seconds (named here a weak electric stimulus) and the other was 10 msec 10 Hz pulse waves at 15 volts for 90 seconds (named a strong electric stimulus) We applied these stimuli to the deep nuchal muscles of rabbits through anodic and cathodic needle electrodes. These electrodes were inserted into the middle of the deep nuchal muscles at the level of the 2nd cervical vertebra, the anodic needle 1 cm above the cathodic one

2. *Optokinetic Stimulus and Experimental Animals*

To produce an optokinetic stimulus the optic cylinder described by Fukuda et al. was used (Fukuda et al. 1957) This is a hollow cylinder 2 m in diameter and 1 9 m in height hung from the ceiling. It was covered with white cloth with 16 black vertical stripes 4 cm wide, at equal distances apart on the inner surface. It was rotated with an angular acceleration of 1 /sec² from zero to a maximum of 180 /sec Adult non-albino rabbits were used in this experiment Their head trunk and limbs were fixed in an animal holder and then they were given the optokinetic stimulation described above

In experiment I rabbits with binocular vision were given an optokinetic stimulus produced by clockwise rotation of the optic cylinder In experiment II rabbits with monocular vision were given an optokinetic stimulus by rotation in the direction from the blindfolded eye to the open eye

3 *Estimation of the Effects of Electric Stimulation of the Neck Muscles on Development of Optokinetic Eye Reflexes*

To evaluate the effects of electric stimulation of the neck muscles on the development of optokinetic eye reflexes, we first made ENG recordings of optokinetic nystagmus and optokinetic after nystagmus before and after electric stimulation and compared the results.

To study changes in optokinetic nystagmus recorded by the ENG in more detail, the period during which the optic cylinder was rotated from zero to a maximum of 180°/sec was divided into 9 sub-periods, and the number of jerks of nystagmus in each sub-period was counted to determine the velocity of cylinder rotation giving the maximum frequency of nystagmus.

Optokinetic after nystagmus was recorded in a dark room. This nystagmus was divided into two types. In the first type optokinetic after nystagmus jerks are in the same direction as those of optokinetic nystagmus, while in the second type they are in the opposite direction.

4 *Results*

(i) EXPERIMENT I

(a) Weak electric stimulation of the neck muscles

1 *Representative cases* Rabbit No 1 Fig. 1 shows recordings of optokinetic nystagmus and optokinetic after nystagmus before and after weak electric stimulation of the deep nuchal muscles of a rabbit with binocular vision. Before electric stimulation optokinetic nystagmus of medium amplitude developed to the left. However it decreased in frequency and amplitude as the velocity of cylinder rotation increased and a total of 48 jerks were observed in 180 seconds. The velocity of cylinder rotation giving the maximum frequency of nystagmus was between 81 /sec and 100°/sec The ENG at the bottom of Fig. 1 shows optokinetic nystagmus and optokinetic after nystagmus following electric stimulation Electric stimulation increased the response significantly A total of 135 jerks were recorded in 180 seconds and the velocity of cylinder rotation giving the maximum frequency of nystagmus was between 121 /sec and 140 /sec No optokinetic after nystagmus was seen before or after electric stimulation.

Rabbit No 2 Fig. 2 shows recordings of optokinetic nystagmus and optokinetic after

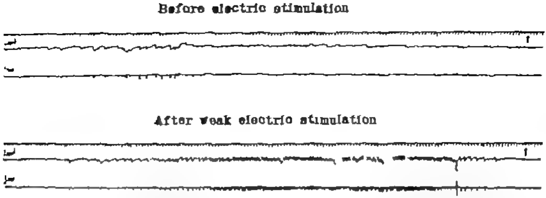

Fig. 1. Optokinetic nystagmus and optokinetic after-nystagmus before and after weak electric stimulation of the deep nuchal muscles of rabbit with binocular vision. Before electric stimulation, optokinetic nystagmus developed fairly well while the velocity of cylinder rotation was low and optokinetic stimuli were enough for the optic organ. However when the velocity of cylinder rotation increased, this nystagmus decreased in frequency and amplitude. After weak electric stimulation, nystagmic responses increased appreciably so that the velocity of cylinder rotation giving the maximum frequency of nystagmus increased. No optokinetic after-nystagmus was seen before or after electric stimulation.

nystagmus before and after weak electric stimulation of the deep nuchal muscles of another rabbit with binocular vision. Before electric stimulation, optokinetic nystagmus of small or medium amplitude developed to the [illegible], but it was inactive during optokinetic stimulation. Five jerks of optokinetic nystagmus were observed in 180 seconds. The velocity of cylinder rotation giving the maximum *frequency* of nystagmus was between 0° and 20°/sec. Optokinetic *after-nystagmus* of medium amplitude developed to the right and showed 7 jerks. The ENG at the bottom of this figure shows optokinetic nystagmus and *optokinetic after* nystagmus after electric stimulation. Again nystagmus increased appreciably: optokinetic nystagmus to 27 jerks in 180 seconds and the velocity of cylinder rotation giving the maximum frequency of nystagmus *to between 21 /sec* and 40 sec. One jerk of optokinetic after-nystagmus was seen to the right.

2. *Results in other animals.* Table 1 shows results of weak electric stimulation of the neck muscles in 8 other rabbits. Electric *stimulation* increased the total number of nystagmic jerks in 6 of the 8 *animals* and raised the velocity of cylinder rotation giving the maximum frequency of nystagmus in all of these 6 animals. However *it reduced the frequency of nystagmic jerks in* 2 rabbits and in one of these it decreased the velocity *of cylinder rotation giving the maximum* frequency of nystagmus.

Results on changes in the relationship between optokinetic *nystagmus and optokinetic after* nystagmus caused by weak electric stimulation of the neck muscles were as follows. Six of the *8 rabbits showed increased optokinetic nystagmus*, with and without decrease in optokinetic after nystagmus. Incidentally, only 2 of these 6 rabbits showed *optokinetic after nystagmus* before electric stimulation. Two of the 8 rabbits *showed* inhibition of optokinetic nystagmus with no sign of development of *optokinetic after* nystagmus. Moreover after weak electric stimulation, 3 rabbits showed abolition of the *inversion* phenomenon of optokinetic nystagmus *in* parallel with promotion of this nystagmus.

(b) *Strong electric stimulation of the neck muscles*

1. *Representative cases.* Rabbit No. 11. Fig. 3 shows recordings of optokinetic nystagmus and optokinetic after nystagmus before and after *strong electric stimulation* of the deep nuchal muscles of a rabbit with binocular vision. Be-

EXPERIMENTAL

1 *Method of Electric Stimulation of the Neck Muscles*

We applied two kinds of electric stimuli one was 10 msec 10 Hz pulse waves, at 1 volt for 90 seconds (named here a weak electric stimulus) and the other was 10 msec 10 Hz pulse waves, at 15 volts for 90 seconds (named a strong electric stimulus) We applied these stimuli to the deep nuchal muscles of rabbits through anodic and cathodic needle electrodes. These electrodes were inserted into the middle of the deep nuchal muscles at the level of the 2nd cervical vertebra, the anodic needle 1 cm above the cathodic one

2. *Optokinetic Stimulus and Experimental Animals*

To produce an optokinetic stimulus the optic cylinder described by Fukuda et al was used (Fukuda et al 1957) This is a hollow cylinder 2 m in diameter and 1 9 m in height hung from the ceiling. It was covered with white cloth with 16 black vertical stripes, 4 cm wide at equal distances apart on the inner surface It was rotated with an angular acceleration of 1 /sec^2 from zero to a maximum of 180°/sec Adult non albino rabbits were used in this experiment. Their head trunk and limbs were fixed in an animal holder and then they were given the optokinetic stimulation described above.

In experiment I rabbits with binocular vision were given an optokinetic stimulus produced by clockwise rotation of the optic cylinder In experiment II rabbits with monocular vision were given an optokinetic stimulus by rotation in the direction from the blindfolded eye to the open eye

3 *Estimation of the Effects of Electric Stimulation of the Neck Muscles on Development of Optokinetic Eye Reflexes*

To evaluate the effects of electric stimulation of the neck muscles on the development of optokinetic eye reflexes, we first made ENG recordings of optokinetic nystagmus and optokinetic after nystagmus before and after electric stimulation and compared the results.

To study changes in optokinetic nystagmus recorded by the ENG in more detail the period during which the optic cylinder was rotated from zero to a maximum of 180°/sec was divided into 9 sub-periods, and the number of jerks of nystagmus in each sub-period was counted to determine the velocity of cylinder rotation giving the maximum frequency of nystagmus.

Optokinetic after nystagmus was recorded in a dark room. This nystagmus was divided into two types. In the first type optokinetic after nystagmus jerks are in the same direction as those of optokinetic nystagmus, while in the second type they are in the opposite direction

4 *Results*

(i) EXPERIMENT I

(a) Weak electric stimulation of the neck muscles

1 *Representative cases* Rabbit No 1 Fig. 1 shows recordings of optokinetic nystagmus and optokinetic after nystagmus before and after weak electric stimulation of the deep nuchal muscles of a rabbit with binocular vision Before electric stimulation optokinetic nystagmus of medium amplitude developed to the left. However it decreased in frequency and amplitude as the velocity of cylinder rotation increased and a total of 48 jerks were observed in 180 seconds. The velocity of cylinder rotation giving the maximum frequency of nystagmus was between 81 /sec and 100°/sec. The ENG at the bottom of Fig. 1 shows optokinetic nystagmus and optokinetic after nystagmus following electric stimulation. Electric stimulation increased the response significantly A total of 135 jerks were recorded in 180 seconds and the velocity of cylinder rotation giving the maximum frequency of nystagmus was between 121 /sec and 140°/sec. No optokinetic after nystagmus was seen before or after electric stimulation.

Rabbit No 2 Fig. 2 shows recordings of optokinetic nystagmus and optokinetic after

Table I. *Changes in optokinetic nystagmus and optokinetic after-nystagmus caused by weak electric stimulation of the neck muscles of rabbits with binocular vision*

Inverted optokinetic nystagmus

Optokinetic after nystagmus developed to the right and showed 2 jerks.

Rabbit No. 12. Fig. 4 shows recordings of optokinetic nystagmus and optokinetic after nystagmus before and after strong electric stimulation of the neck muscles of another rabbit with binocular vision. Before electric stimulation, the animal developed inactive optokinetic nystagmus showing 7 jerks of optokinetic nystagmus in 180 seconds and the maximum frequency of nystagmus at a velocity of cylinder rotation of between 0° and 20 /sec. Optokinetic after-nystagmus of medium amplitude occurred to the right and showed one jerk. The ENG at the bottom of this figure shows optokinetic nystagmus and optokinetic after nystagmus following electric stimulation. The animal developed optokinetic nystagmus of small amplitude to the left when the velocity of cylinder rotation was low but at increased velocity nystagmus to the left disappeared and the inversion phenomenon appeared. Thus, 20 jerks of optokinetic nystagmus were recorded, 11 to the left and 9 to the right (i.e., inverted optokinetic nystagmus). The velocity of cylinder rotation giving the maximum frequency of nystagmus was between 0° and 20 /sec. Optokinetic after nystagmus developed to the right and showed 13 jerks.

Rabbit No. 13. Fig. 5 shows recordings of optokinetic nystagmus and optokinetic after nystagmus before and after strong electric stimulation of the deep nuchal muscles of another rabbit with binocular vision. Before electric stimulation, the animal developed fairly active optokinetic nystagmus showing 29 jerks in 180 seconds. The velocity of cylinder rotation giving the maximum frequency of nystagmus was between 0° and 20 /sec. No optokinetic after nystagmus was observed. After electric stimulation (ENG at bottom of Fig. 5) responses increased markedly to 237 jerks of optokinetic

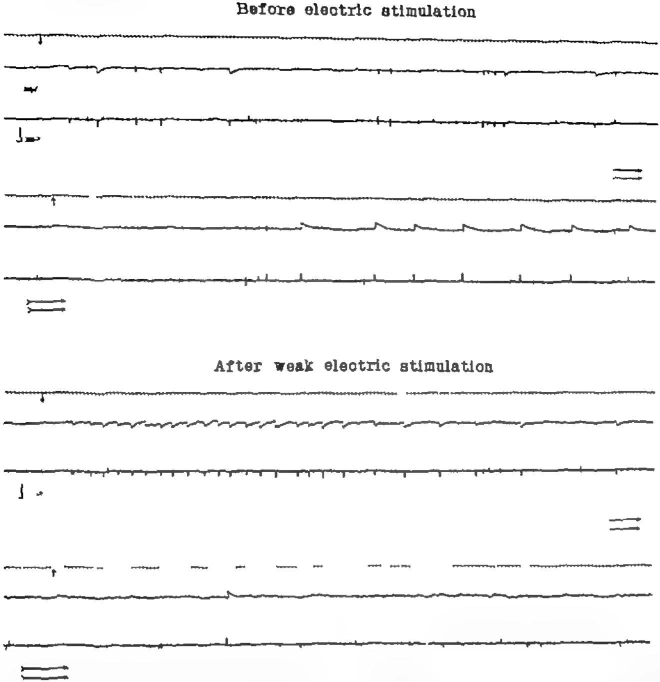

Fig 2 Optokinetic nystagmus and optokinetic after nystagmus before and after weak electric stimulation of the deep nuchal muscles of a rabbit with binocular vision. Before electric stimulation, optokinetic nystagmus was inactive, with fairly active optokinetic after-nystagmus. After weak electric stimulation, nystagmic responses increased, so that the velocity of cylinder rotation giving the maximum frequency of nystagmus increased. Furthermore, optokinetic after-nystagmus decreased appreciably and showed one jerk

fore electric stimulation, optokinetic nystagmus of medium amplitude occurred to the left and was fairly active during optokinetic stimulation. Thirty jerks of optokinetic nystagmus were observed in 180 seconds The velocity of cylinder rotation giving the maximum frequency of nystagmus was between 21 /sec and 40 /sec. No optokinetic after nystagmus was observed. The ENG at the bottom of this figure shows that electric stimulation reduced optokinetic nystagmus 16 jerks of optokinetic nystagmus were recorded in 180 seconds and the velocity of cylinder rotation giving the maximum frequency of nystagmus was between 0° and 20 /sec.

Table I. *Changes in optokinetic nystagmus and optokinetic after-nystagmus caused by weak electric stimulation of the neck muscles of rabbits with binocular vision*

Case	Electric stimulation	Optokinetic nystagmus: 0°–20°	21–40°	41–60°	61–80°	81°–100°	101–120°	121–140°	141–160°	161–180	Total nystagmus jerks	Velocity of cylinder rotation giving the maximum frequency of nystagmus	Optokinetic after-nystagmus: 1st type	2nd type	Total nystagmus jerks

Inverted optokinetic nystagmus

Optokinetic after-nystagmus developed to the right and showed 2 jerks.

Rabbit No. 12: Fig. 4 shows recordings of optokinetic nystagmus and optokinetic after nystagmus before and after strong electric stimulation of the neck muscles of another rabbit with binocular vision. Before electric stimulation, the animal developed inactive optokinetic nystagmus showing 7 jerks of optokinetic nystagmus in 180 seconds and the maximum frequency of nystagmus at a velocity of cylinder rotation of between 0° and 20°/sec. Optokinetic after-nystagmus of medium amplitude occurred to the right and showed one jerk. The ENG at the bottom of this figure shows optokinetic nystagmus and optokinetic after-nystagmus following electric stimulation. The animal developed optokinetic nystagmus of small amplitude to the left when the velocity of cylinder rotation was low but at increased velocity nystagmus to the left disappeared and the inversion phenomenon appeared. Thus, 20 jerks of optokinetic nystagmus were recorded, 11 to the left and 9 to the right (i.e., inverted optokinetic nystagmus). The velocity of cylinder rotation giving the maximum frequency of nystagmus was between 0° and 20°/sec. Optokinetic after nystagmus developed to the right and showed 13 jerks.

Rabbit No. 13: Fig. 5 shows recordings of optokinetic nystagmus and optokinetic after nystagmus before and after strong electric stimulation of the deep nuchal muscles of another rabbit with binocular vision. Before electric stimulation, the animal developed fairly active optokinetic nystagmus showing 29 jerks in 180 seconds. The velocity of cylinder rotation giving the maximum frequency of nystagmus was between 0° and 20°/sec. No optokinetic after nystagmus was observed. After electric stimulation (ENG at bottom of Fig. 5) responses increased markedly to 237 jerks of optokinetic

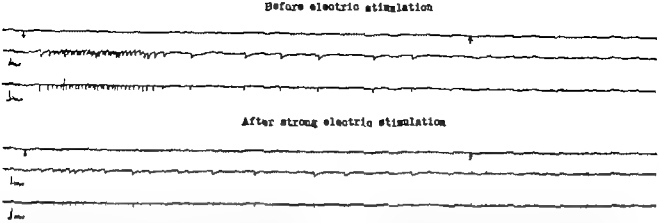

Fig 3 Optokinetic nystagmus and optokinetic after nystagmus before and after strong electric stimulation of the deep nuchal muscles of a rabbit with binocular vision. Before electric stimulation, optokinetic nystagmus developed fairly well, although nystagmic responses decreased when the velocity of cylinder rotation increased. After strong electric stimulation, nystagmic responses decreased appreciably in frequency and amplitude, so that the velocity of cylinder rotation giving the maximum *frequency of nystagmus* decreased. No *optokinetic after* nystagmus was observed before electric stimulation. However *optokinetic* after-nystagmus developed to the right and showed two jerks after electric stimulation.

nystagmus in 180 seconds and the maximum *frequency of nystagmus at a* velocity of cylinder rotation of between 141 /sec and 160 /sec Marked optokinetic after nystagmus also developed to the left showing so called optokinetic nystagmus firing and 94 jerks were recorded

2 *Results in other animals* Table II shows results of strong electric stimulation of the neck muscles in 7 other rabbits Five of these 7 rabbits showed decrease in the total number of nystagmic jerks and 3 of these 5 rabbits also showed the maximum frequency of nystagmus at a decreased velocity of cylinder rotation The sixth rabbit showed no appreciable change in optokinetic nystagmus except that it developed inverted optokinetic nystagmus. The remaining rabbit showed increased optokinetic nystagmus after electric stimulation with increase in the total number of nystagmic jerks and in the velocity of cylinder rotation giving the maximum frequency of nystagmus.

Results on changes in the relationship between optokinetic nystagmus and optokinetic after nystagmus caused by strong electric stimulation

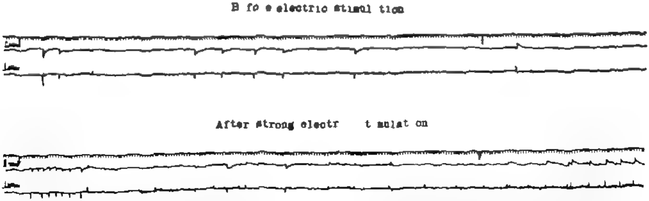

Fig 4 Optokinetic nystagmus and optokinetic after nystagmus before and after strong electric stimulation of the deep nuchal muscles of a rabbit with binocular vision. Before electric stimulation, optokinetic nystagmus was rather inactive. Optokinetic after-nystagmus developed to the right and showed one jerk. After strong electric stimulation, optokinetic nystagmus developed to the left when the velocity of cylinder rotation was low However when the velocity increased, nystagmus to the left disappeared and the inversion phenomenon developed. Optokinetic after-nystagmus to the right appeared and showed 13 jerks.

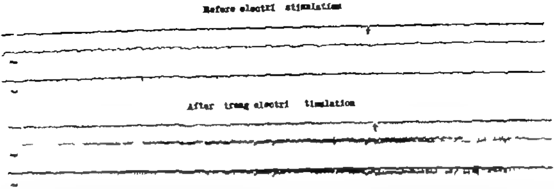

Fig. 3. Optokinetic nystagmus and optokinetic after-nystagmus before and after strong electric stimulation of the deep nuchal muscles of a rabbit with binocular vision. Before electric stimulation, optokinetic nystagmus developed fairly well, although it decreased in frequency when the velocity of cylinder rotation increased. After strong electric stimulation, optokinetic nystagmus increased markedly so that the velocity of cylinder rotation giving the maximum frequency of nystagmus increased. Furthermore, optokinetic after-nystagmus increased greatly. That is, "optokinetic nystagmus firing" developed after strong electric stimulation.

were as follows. 3 of the 7 rabbits showed inhibition of optokinetic nystagmus, but no optokinetic after-nystagmus either before or after strong electric stimulation. Two other rabbits showed inhibition of optokinetic nystagmus and increase in optokinetic after nystagmus. The sixth rabbit showed no appreciable change in the total number of optokinetic nystagmus, but showed a marked increase in optokinetic after nystagmus as well as development of inverted optokinetic nystagmus. The remaining case showed increased optokinetic nystagmus and inhibited optokinetic after nystagmus. Furthermore, 3 rabbits showed development or increase

Inverted optokinetic nystagmus

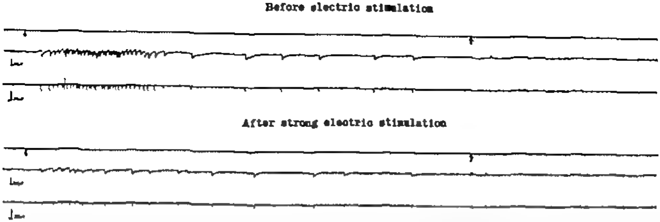

Fig 3 Optokinetic nystagmus and optokinetic after nystagmus before and after strong electric stimulation of the deep nuchal muscles of a rabbit with binocular vision. Before electric stimulation, optokinetic nystagmus developed fairly well, although nystagmic responses decreased when the velocity of cylinder rotation increased. After strong electric stimulation, nystagmic responses decreased appreciably in frequency and amplitude, so that the velocity of cylinder rotation giving the maximum frequency of nystagmus decreased. No optokinetic after nystagmus was observed before electric stimulation. However optokinetic after-nystagmus developed to the right and showed two jerks after electric stimulation.

nystagmus in 180 seconds and the maximum frequency of nystagmus at a velocity of cylinder rotation of between 141 /sec and 160°/sec. Marked optokinetic after nystagmus also developed to the left showing so called "optokinetic nystagmus firing" and 94 jerks were recorded

2. *Results in other animals* Table II shows results of strong electric stimulation of the neck muscles in 7 other rabbits. Five of these 7 rabbits showed decrease in the total number of nystagmic jerks and 3 of these 5 rabbits also showed the maximum frequency of nystagmus at a decreased velocity of cylinder rotation The sixth rabbit showed no appreciable change in optokinetic nystagmus except that it developed inverted optokinetic nystagmus. The remaining rabbit showed increased optokinetic nystagmus after electric stimulation with increase in the total number of nystagmic jerks and in the velocity of cylinder rotation giving the maximum frequency of nystagmus.

Results on changes in the relationship between optokinetic nystagmus and optokinetic after nystagmus caused by strong electric stimulation

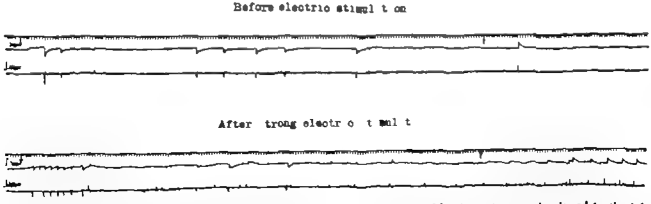

Fig 4 Optokinetic nystagmus and optokinetic after nystagmus before and after strong electric stimulation of the deep nuchal muscles of a rabbit with binocular vision. Before electric stimulation, optokinetic nystagmus was rather inactive. Optokinetic after-nystagmus developed to the right and showed one jerk. After strong electric stimulation, optokinetic nystagmus developed to the left when the velocity of cylinder rotation was low. However when the velocity increased, nystagmus to the left disappeared and the inversion phenomenon developed. Optokinetic after-nystagmus to the right appeared and showed 13 jerks.

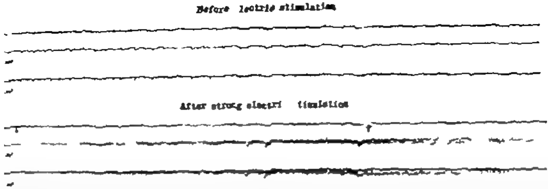

Fig. 3. Optokinetic nystagmus and optokinetic after-nystagmus before and after strong electric stimulation of the deep nuchal muscles of rabbit with binocular vision. Before electric stimulation, optokinetic nystagmus developed fairly well, although it decreased in frequency as the velocity of cylinder rotation increased. After strong electric stimulation, optokinetic nystagmus increased markedly so that the velocity of cylinder rotation giving the maximum frequency of nystagmus increased. Furthermore, optokinetic after-nystagmus increased greatly. That is, optokinetic nystagmus firing developed after strong electric stimulation.

were as follows. 3 of the 7 rabbits showed inhibition of optokinetic nystagmus, but no optokinetic after-nystagmus either before or after strong electric stimulation. Two other rabbits showed inhibition of optokinetic nystagmus and increase in optokinetic after-nystagmus. The sixth rabbit showed no appreciable change in the total number of optokinetic nystagmus, but showed a marked increase in optokinetic after nystagmus as well as development of inverted optokinetic nystagmus. The remaining case showed increased optokinetic nystagmus and inhibited optokinetic after nystagmus. Further more, 3 rabbits showed development or increase

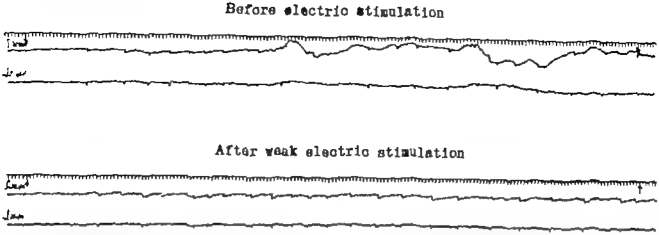

Fig 6 Optokinetic nystagmus and optokinetic after nystagmus before and after weak electric stimulation of the deep nuchal muscles of a rabbit with monocular vision. Before electric stimulation, optokinetic nystagmus developed fairly well when the velocity of cylinder rotation was low However it became irregular and inactive as the velocity of cylinder rotation increased. Optokinetic after-nystagmus developed to the left and showed one jerk. After weak electric stimulation, optokinetic nystagmus became regular and increased in frequency and amplitude. No optokinetic after-nystagmus was observed.

in the inversion phenomenon of optokinetic nystagmus, with or without reduction in the total number of nystagmic jerks of this nystagmus after strong electric stimulation

(ii) EXPERIMENT II

1 *Representative cases* Rabbit No 21 Fig. 6 shows recordings of optokinetic nystagmus and optokinetic after nystagmus before and after weak electric stimulation of the deep nuchal muscles of a rabbit with monocular vision. Before electric stimulation optokinetic nystagmus was fairly regular when the velocity of cylinder rotation was low However it became irregular and inactive as the velocity of cylinder rotation increased A total of 14 jerks of optokinetic nystagmus were recorded in 180 seconds. The velocity of cylinder rotation giving the maximum frequency of nystagmus was between 21 /sec and 40 /sec. Optokinetic after nystagmus developed to the left and showed one jerk. The ENG at the bottom of this figure shows that after electric stimulation, the animal developed fairly regular optokinetic nystagmus in response to an increased velocity of cylinder rotation and 26 jerks of optokinetic nystagmus were recorded in 180 seconds. The velocity of cylinder rotation giving the maximum frequency of nystagmus was between 21 /sec and 40°/sec. No optokinetic after nystagmus was observed

Rabbit No 22 Fig. 7 shows recordings of optokinetic nystagmus and optokinetic after nystagmus before and after weak electric stimulation of the deep nuchal muscles of a rabbit with monocular vision Before electric stimulation the animal showed inactive optokinetic nystagmus in response to an optokinetic stimulus moving in the direction from the blindfolded eye to the open eye. No optokinetic nystagmus was observed when the velocity of cylinder rotation increased So only 8 jerks of optokinetic nystagmus were recorded in 180 seconds. The velocity of cylinder rotation giving the maximum frequency of nystagmus was between 0 and 20°/sec. No optokinetic after nystagmus was observed. The ENG at the bottom of this figure shows optokinetic nystagmus and optokinetic after nystagmus following electric stimulation The animal developed very inactive optokinetic nystagmus with a low frequency and amplitude. Furthermore it showed the inversion phenomenon of optokinetic nystagmus as the velocity of cylinder rotation increased. Thus, 5 jerks of optokinetic nystagmus were recorded, 2 to the left and 3 to the right (i e., inverted optokinetic nystagmus) The velocity of cylinder rotation giving the maximum frequency of nystagmus was

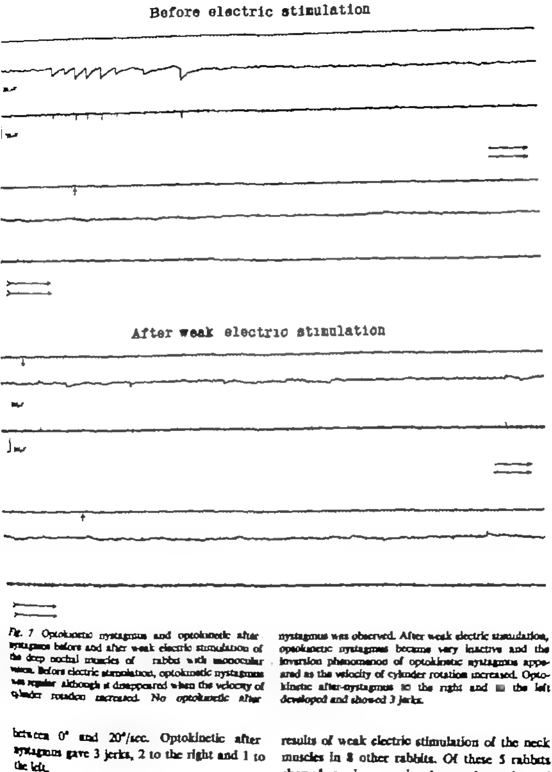

Fig. 7. Optokinetic nystagmus and optokinetic after-nystagmus before and after weak electric stimulation of the deep nuchal muscles of rabbit with monocular vision. Before electric stimulation, optokinetic nystagmus was regular although it disappeared when the velocity of cylinder rotation increased. *No optokinetic after-nystagmus was observed.* After weak electric stimulation, optokinetic nystagmus became very inactive and the inversion phenomenon of optokinetic nystagmus appeared as the velocity of cylinder rotation increased. Optokinetic after-nystagmus to the right and to the left *developed and showed 3 jerks.*

between 0° and 20°/sec. Optokinetic after nystagmus gave 3 jerks, 2 to the right and 1 to the left.

2. *Results in other animals.* Table III shows results of weak electric stimulation of the neck muscles in 8 other rabbits. Of these 5 rabbits showed an increase in the total number of nystagmic jerks after the stimulation, although

*: Inverted optokinetic nystagmus

increase in the velocity of cylinder rotation giving the maximum frequency of nystagmus was less obvious. Only one rabbit showed a decrease in the total number of nystagmic jerks and in the velocity of cylinder rotation giving the maximum frequency of nystagmus. The other two showed the inversion phenomenon of optokinetic nystagmus, with and without increase in the total number of nystagmic jerks of this nystagmus.

Results on changes in the relationship between optokinetic nystagmus and optokinetic after nystagmus caused by weak electric stimulation were as follows. Five of the 8 rabbits showed promotion of optokinetic nystagmus, without any appreciable change in optokinetic after nystagmus following electric stimulation. One of the 8 rabbits showed inhibition of optokinetic nystagmus and marked intensification of pre-existing optokinetic after nystagmus. The other two showed inverted optokinetic nystagmus and one of these developed a marked optokinetic after nystagmus.

COMMENT

(1) Correlation between the intensity of electric stimuli given to the deep nuchal muscles and resulting changes in optokinetic eye reflexes

In the present work rabbits with binocular vision tended to show increased optokinetic nystagmus when a weak electric stimulus was given to the neck muscles. In contrast, when a strong stimulus was given, similar rabbits tended to show inhibition of optokinetic nystagmus or in some cases, the inversion phenomenon. These results suggest that there is a close relationship between the optic organ and the cervical proprioceptors in maintenance of body equilibrium and that the cervical proprioceptors can function in two opposing mechanisms which result in either increase or decrease in equilibrium function of the optokinetic system. That is, the mechanism resulting in increased equilibrium function of the optokinetic system seems to be correlated intimately with adequate excita

tion of the cervical proprioceptors, while the mechanism resulting in decreased function seems to be closely correlated with over-excitement of these receptors. It is of great importance that the proprioceptors, which originally act to promote equilibrium function of the eye and body can produce dysfunction of the optokinetic system if these receptors show over-excitement in response to strong electric stimulation. These characteristics of the proprioceptors are essentially similar to those of the labyrinth, which were originally found by Fukuda and were analyzed under the concept of "two phases of the labyrinthine reflex" (Fukuda 1958*a*, *b*).

In short, it is, we feel, valuable to have clarified that Fukuda's concept of the labyrinthine reflex is applicable in interpreting the proprioceptive reflexes from the standpoint of body equilibrium. Furthermore, the fact that strong electric stimulation of the deep nuchal muscles can induce abnormal optokinetic eye reflexes, such as inactive optokinetic nystagmus and inverted optokinetic nystagmus, is helpful in understanding the mechanism of vertigo of cervical origin, since we can often see such abnormal optokinetic eye reflexes in cases with whiplash injury who complained of neck pain and vertigo.

(2) Correlation between optokinetic nystagmus and optokinetic after nystagmus in relation to the activity of the cervical proprioceptors, and the organ of optokinetic after-nystagmus

The present work showed that electric stimulation of the deep nuchal muscles of rabbits affected both the development of optokinetic nystagmus and optokinetic after nystagmus, and that promotion of optokinetic after nystagmus tended to be accompanied by inhibition of optokinetic nystagmus or in some cases, by the appearance of inverted optokinetic nystagmus. In contrast, inhibition of optokinetic after nystagmus tended to appear in parallel with promotion of optokinetic nystagmus. Furthermore, the former finding was often observed on strong electric stimulation of the neck muscles, while the latter was observed on weak electric stimulation.

Optokinetic nystagmus is believed to be the ocular equilibrium reflex which maintains a moving object in the fovea, and consequently enables the subject to adapt to rapid changes of the surroundings. However the physiological significance of optokinetic after nystagmus has not been studied from the standpoint of body equilibrium. So it is, we feel, valuable to have clarified that optokinetic after nystagmus differs greatly in behavior from optokinetic nystagmus in relation to the activity of the cervical proprioceptors. From this fact, we can say that first, optokinetic after-nystagmus can be regarded as a sign of dysfunction of the optokinetic system from the standpoint of body equilibrium and second, the cervical proprioceptors, as an organ of equilibrium, can exert two different actions on the optokinetic eye reflexes, i.e., promotion of optokinetic nystagmus and inhibition of optokinetic after-nystagmus.

It is generally believed that marked inhibition of optokinetic nystagmus or inverted optokinetic nystagmus is due to dysfunction of the central nervous system, particularly the brain stem reticular formation. The present examinations revealed that optokinetic after-nystagmus tended to appear or increase in parallel with inhibition of optokinetic nystagmus or in some cases, it was accompanied by the appearance or intensification of inverted optokinetic nystagmus. Furthermore, Hinoki found from studies on the EEG that the strong electric stimulus used in this experiment when applied to the deep nuchal muscles of rabbits can produce dysfunction of the brain stem reticular formation (Hinoki, 1970). From these facts, it seems that optokinetic after-nystagmus, of both the 1st and 2nd types, is of central origin and is especially correlated with dysfunction of the brain stem reticular formation. This consideration is compatible with opinions of many workers since the work of Bárány. Naturally the brain stem should not be considered as uniquely responsible for the formation of optokinetic after nystagmus, because Morimoto et al. (1963) found that the cerebrum and the cerebellum are also correlated with the formation of this.

(3) Effects of electric stimulation of the deep

Monocular vision	1V 90	3	0	0	1	1	1	2	1	0

the appearance or intensification of optokinetic after-nystagmus.

(2) The appearance or intensification of this phenomenon tended to develop in parallel with inhibition of optokinetic nystagmus. It was also fairly well correlated with development or intensification of optokinetic after-nystagmus.

(3) When weak electric stimulation was given to the deep nuchal muscles of rabbits with binocular vision, the animals showed the phenomena described in (1). In contrast, when strong electric stimulation was given to the same muscles, the animals tended to show the phenomena described in (2). On weak electric stimulation of the same muscles of rabbits with monocular vision, some rabbits developed inverted optokinetic nystagmus, which was fairly well correlated with the appearance or intensification of optokinetic after-nystagmus. However a less clear correlation was found between inverted optokinetic nystagmus and optokinetic nystagmus in these animals.

Hinoki, one of the present authors, found that after weak electric stimulation of the neck muscles, many rabbits with binocular vision showed an arousal reaction in the EEG in response to optokinetic stimulation, whereas after strong electric stimulation, similar rabbits tended to show a sluggish arousal reaction in the EEG (Hinoki, 1972).

Rabbits with monocular vision also tended to show activation of the EEG in response to optokinetic stimulation after weak electric stimulation of the neck muscles. However the arousal reaction in the EEG was less obvious in these animals. Furthermore, a few of these animals showed reduction in the arousal reaction (Hinoki et al., to be published).

These results suggest that the inversion phenomenon of optokinetic nystagmus seen in the present experiments is due to dysfunction of the brain stem reticular formation, which is mainly induced by over-excitement of the cervical proprioceptors.

Morimoto and his co-workers found that when accelerative optokinetic stimulation was given repeatedly at short intervals, several rabbits developed eye movements resembling "nystagmus clonus" or "firing" in which nystagmus occurred very actively and independently of the original optokinetic stimuli and lasted for a long time after cessation of optokinetic stimulation (Morimoto et al., 1963). They also found that this phenomenon was more easily elicited after removal of the brain cortex of rabbits (Morimoto et al., 1963). In our experiments, this phenomenon was never observed in rabbits with inactive optokinetic nystagmus before electric stimulation of the neck muscles. Furthermore, it only developed on strong electric stimulation. Bender

nuchal muscles on the unidirectional responsiveness of the eye to optokinetic stimulation in rabbits with one eye

Fukuda & Tokita found that animals with completely crossed optic nerves, such as fowls and rabbits, develop very inactive optokinetic eye and body reflexes when they are given optokinetic stimuli moving from the side of the blindfolded eye to that of the open eye. Of course, they can respond appreciably to an optokinetic stimulus in the opposite direction. Fukuda named this phenomenon the unidirectionality of the optokinetic reflex (Fukuda & Tokita, 1957). This unidirectional responsiveness of the eye to optokinetic stimulation can be significantly improved by simultaneous application of a weak labyrinthine stimulation and the animals then respond fairly well to optokinetic stimuli to which the optic organ alone cannot react (Fukuda, 1959)

The question then arises of whether the cervical proprioceptors can exert a similar function to that of the labyrinth just mentioned The present examinations revealed that after weak electric stimulation of the deep nuchal muscles, about half of the rabbits with monocular vision responded fairly well to an optokinetic stimulus moving from the side of the blindfolded eye to that of the open eye and consequently showed promotion of optokinetic nystagmus. This means that the cervical proprioceptors can participate in the compensatory mechanism of the unidirectional responsiveness of the eye to optokinetic stimulation in rabbits with one eye However this compensatory mechanism of the cervical proprioceptors is not effective enough to allow rabbits with monocular vision to respond well to an optokinetic stimulus moving from the side of the blindfolded eye to that of the open eye For example, promotion of optokinetic nystagmus caused by weak electric stimulation was less obvious in these animals. Furthermore some of these animals showed inverted optokinetic nystagmus as well as activation of optokinetic after nystagmus. Naturally in the daily life of rabbits with one eye not only the cervical proprioceptors but also the labyrinth can participate in the compensatory mechanism of the unidirectional responsiveness of the eye to optokinetic stimulation at times such as during active rotation. Thus, animals with one eye can respond well to an optokinetic stimulus moving from the blindfolded eye to that of the open eye. This assumption is supported by the fact that after weak electric stimulation of the deep nuchal muscles, many rabbits with one eye show active perrotatory eye nystagmus in response to a rotatory stimulus produced by subliminal rotation from the side of the open eye to that of the blindfolded eye (Koike, 1971). Of course, during such rotation, rabbits with one eye receive an optokinetic stimulus from the side of the blindfolded eye to that of the open eye, which is induced by relative movements of the external world due to chair rotation.

(4) The inversion phenomenon of optokinetic nystagmus and so called "optokinetic nystagmus firing in relation to the activity of the cervical proprioceptors

The inversion phenomenon of optokinetic nystagmus is sometimes observed in patients with lesions of the brain stem such as brain tumor head trauma and circulatory disorders of this part of the brain The following observations have been made on the relationship between this phenomenon and the activity of the cervical proprioceptors. Ushio one of our coworkers, found that the inversion phenomenon of optokinetic nystagmus was observed in vertigo cases with whiplash injury and that this phenomenon seemed to have a positive correlation with hypertonicity of the cervical erector muscles (Ushio et al., 1971) However no systematic and experimental studies have been made from this point of view Table IV shows changes in the correlation between optokinetic nystagmus, optokinetic after nystagmus and inverted optokinetic nystagmus caused by electric stimulation of the neck muscles. From this table the following conclusions are drawn

(1) Disappearance of inverted optokinetic nystagmus was parallel with promotion of optokinetic nystagmus. Furthermore disappearance of this phenomenon was :

Table IV *Changes in correlations between inverted optokinetic nystagmus optokinetic nystagmus and optokinetic after-nystagmus caused by electric stimulation of the neck muscles of rabbits*

[illegible]		Inverted optokinetic nystagmus			Optokinetic nystagmus			Optokinetic after-nystagmus		
		Appearance or Increase	No significant change	Disappearance or Decrease	Increase	No significant change	Decrease	Appearance or Increase	No significant change	Disappearance or Decrease
Binocular vision	1V; 90	0	0	3	3	0	0	0	3	0
	15V; 90	4	0	0	0	2	2	3	1	0
Monocular vision	1V 90	3	0	0	1	1	1	2	1	0

the appearance or intensification of optokinetic after-nystagmus.

(2) The appearance or intensification of this phenomenon tended to develop in parallel with inhibition of optokinetic nystagmus. It was also fairly well correlated with development or intensification of optokinetic after nystagmus.

(3) When weak electric stimulation was given to the deep nuchal muscles of rabbits with binocular vision, the animals showed the phenomena described in (1). In contrast, when strong electric stimulation was given to the same muscles, the animals tended to show the phenomena described in (2). On weak electric stimulation of the same muscles of rabbits with monocular vision, some rabbits developed inverted optokinetic nystagmus, which was fairly well correlated with the appearance or intensification of optokinetic after-nystagmus. However a less clear correlation was found between inverted optokinetic nystagmus and optokinetic nystagmus in these animals.

Ishida, one of the present authors, found that after weak electric stimulation of the neck muscles, many rabbits with binocular vision showed an arousal reaction in the EEG in response to optokinetic stimulation, whereas after strong electric stimulation, similar rabbits tended to show a sluggish arousal reaction in the EEG (Ishida, 1972).

Rabbits with monocular vision also tended to show activation of the EEG in response to optokinetic stimulation after weak electric stimulation of the neck muscles. However the arousal reaction in the EEG was less obvious in these animals. Furthermore, a few of these animals showed reduction in the arousal reaction (Hinoki et al., to be published).

These results suggest that the inversion phenomenon of optokinetic nystagmus seen in the present experiments is due to dysfunction of the brain stem reticular formation, which is mainly induced by over-excitement of the cervical proprioceptors.

Morimoto and his co-workers found that when accelerative optokinetic stimulation was given repeatedly at short intervals, several rabbits developed eye movements resembling "nystagmus clonus" or "firing" in which nystagmus occurred very actively and independently of the original optokinetic stimuli and lasted for a long time after cessation of optokinetic stimulation (Morimoto et al., 1963). They also found that this phenomenon was more easily elicited after removal of the brain cortex of rabbits (Morimoto et al., 1963). In our experiments, this phenomenon was never observed in rabbits with inactive optokinetic nystagmus before electric stimulation of the neck muscles. Furthermore, it only developed on strong electric stimulation. Bender

nuchal muscles on the unidirectional responsiveness of the eye to optokinetic stimulation in rabbits with one eye

Fukuda & Tokita found that animals with completely crossed optic nerves such as fowls and rabbits, develop very inactive optokinetic eye and body reflexes when they are given optokinetic stimuli moving from the side of the blindfolded eye to that of the open eye. Of course, they can respond appreciably to an optokinetic stimulus in the opposite direction Fukuda named this phenomenon "the unidirectionality of the optokinetic reflex" (Fukuda & Tokita, 1957). This unidirectional responsiveness of the eye to optokinetic stimulation can be significantly improved by simultaneous application of a weak labyrinthine stimulation and the animals then respond fairly well to optokinetic stimuli to which the optic organ alone cannot react (Fukuda, 1959).

The question then arises of whether the cervical proprioceptors can exert a similar function to that of the labyrinth just mentioned The present examinations revealed that after weak electric stimulation of the deep nuchal muscles, about half of the rabbits with monocular vision responded fairly well to an optokinetic stimulus moving from the side of the blindfolded eye to that of the open eye and consequently showed promotion of optokinetic nystagmus. This means that the cervical proprioceptors can participate in the compensatory mechanism of the unidirectional responsiveness of the eye to optokinetic stimulation in rabbits with one eye. However this compensatory mechanism of the cervical proprioceptors is not effective enough to allow rabbits with monocular vision to respond well to an optokinetic stimulus moving from the side of the blindfolded eye to that of the open eye For example, promotion of optokinetic nystagmus caused by weak electric stimulation was less obvious in these animals. Furthermore, some of these animals showed inverted optokinetic nystagmus as well as activation of optokinetic after nystagmus. Naturally in the daily life of rabbits with one eye not only the cervical proprioceptors but also the labyrinth can participate in the compensatory mechanism of the unidirectional responsiveness of the eye to optokinetic stimulation at times such as during active rotation. Thus, animals with one eye can respond well to an optokinetic stimulus moving from the blindfolded eye to that of the open eye. This assumption is supported by the fact that after weak electric stimulation of the deep nuchal muscles, many rabbits with one eye show active perrotatory eye nystagmus in response to a rotatory stimulus produced by subliminal rotation from the side of the open eye to that of the blindfolded eye (Koike, 1971). Of course, during such rotation, rabbits with one eye receive an optokinetic stimulus from the side of the blindfolded eye to that of the open eye, which is induced by relative movements of the external world due to chair rotation

(4) The inversion phenomenon of optokinetic nystagmus and so called "optokinetic nystagmus firing in relation to the activity of the cervical proprioceptors

The inversion phenomenon of optokinetic nystagmus is sometimes observed in patients with lesions of the brain stem such as brain tumor head trauma and circulatory disorders of this part of the brain. The following observations have been made on the relationship between this phenomenon and the activity of the cervical proprioceptors. Ushio one of our coworkers, found that the inversion phenomenon of optokinetic nystagmus was observed in vertigo cases with whiplash injury and that this phenomenon seemed to have a positive correlation with hypertonicity of the cervical erector muscles (Ushio et al. 1971) However no systematic and experimental studies have been made from this point of view Table IV shows changes in the correlation between optokinetic nystagmus optokinetic after nystagmus and inverted optokinetic nystagmus caused by electric stimulation of the neck muscles From this table the following conclusions are drawn

(1) Disappearance of inverted optokinetic nystagmus was parallel with promotion of optokinetic nystagmus. Furthermore, disappearance of this phenomenon was not accompanied by

formation. Furthermore, this tract changes neurons in these parts of the brain and terminates in the superior colliculus (Nauta & Kuypers, 1958). In addition, this tract sends some fibers to Deiters nucleus (Terada, 1960; Niimi et al., 1960).

On the other hand, neural elements connecting the cervical proprioceptors to the cerebellum involve the cuneocerebellar tract and the spino-olivo-cerebellar tract, especially the former.

In short, impulses from the optic organ and the cervical proprioceptors may be integrated mainly in the brain stem reticular formation, with or without direct collaboration with the cerebellum and the vestibular nuclei. Of course, this idea is based on observations on rabbits. In man and animals, such as monkeys, neural elements of higher order particularly the brain cortex should be taken into consideration in assessing the mechanism of optic proprioceptive coordination. Furthermore, the following mechanism seems important in speculating on this problem. Tokita et al. reported that nystagmogenic areas in the meso-diencephalon, originally found by Lachmann and his co-workers, are important in the formation of optic vestibular coordination (Lachmann et al., 1958, Tokita et al., 1964). These areas seem correlated with production of optic proprioceptive coordination, since the midbrain reticular formation, which is important in eliciting central nystagmus, connects with the cervical proprioceptors through the spinoreticular tract.

Versuch I. Die Auswirkungen schwacher und starker elektrischer Stimulation der tiefen Nackenmuskeln auf die Veränderungen des optokinetischen Nystagmus und des optokinetischen Nachnystagmus wurden bei erwachsenen Non-albino-Kaninchen mit Binokularsehen überprüft.

Versuch II. Versuch I wurde bei Kaninchen mit Monokularsehen wiederholt, wobei ein optokinetischer Reiz von der Seite des verbundenen Auges aus auf die Seite des offenen Auges und nur ein schwacher elektrischer Reiz auf die Nackenmuskeln ausgeübt wurden.

Folgende Resultate wurden erzielt.

1) Versuch I. Schwache elektrische Stimulation der tiefen Nackenmuskeln von Kaninchen mit Binokularsehen zeigte die Tendenz, einen optokinetischen Nystagmus zu fördern, wobei sich entweder keine deutliche Veränderung oder eine Abnahme des optokinetischen Nachnystagmus zeigte. Starke elektrische Stimulation hatte entgegengesetzte Auswirkungen, d. h., dass sich hierbei die Tendenz zeigte, einen optokinetischen Nystagmus zu hemmen und einen optokinetischen Nachnystagmus zu aktivieren. Starke elektrische Stimulation rief ebenfalls einen anomalen optokinetischen Nystagmus hervor, wie z. B. die Inversion des optokinetischen Nystagmus und „die Feuerung des optokinetischen Nystagmus".

2) Versuch II. Schwache elektrische Stimulation der tiefen Nackenmuskeln von Kaninchen mit Monokularsehen hatte ähnliche Auswirkungen wie beim Versuch I. Jedoch war die Förderung des optokinetischen Nystagmus weniger deutlich, während die Aktivierung des optokinetischen Nachnystagmus stärker ausgeprägt war. Ausserdem entwickelte sich die Inversion des optokinetischen Nystagmus sogar bei schwacher elektrischer Stimulation.

Aus diesen Ergebnissen wurden folgende Schlüsse gezogen:

1) Die zervikalen Propriozeptoren können zwei Mechanismen auslösen: Sie können die Gleichgewichtsfunktion des optokinetischen Systems entweder unterstützen oder ausschalten.

2) Die zervikalen Propriozeptoren als Gleichgewichtsorgan können sich in zweifacher Weise auf den optokinetischen Augenreflex auswirken, d. h., sie können den optokinetischen Nystagmus fördern und den optokinetischen Nachnystagmus hemmen.

ACKNOWLEDGEMENTS

The authors are greatly indebted to Professor K. Niimi (Dept. of Anatomy, Okayama Univ.) for valuable advice on fiber connections in the central nervous system. The assistance and helpful discussion of other members of the ENT Department of Tokushima University are gratefully acknowledged.

ZUSAMMENFASSUNG

Zwei Versuche über die funktionelle Korrelation zwischen dem Sehorgan und den zervikalen Propriozeptoren in der Erhaltung des Körpergleichgewichts wurden durchgeführt.

studied optokinetic after nystagmus in monkeys and found that once rythmical eye movements, such as optokinetic nystagmus, are set up, they continue of their own accord and become relatively independent of the optokinetic stimuli with regard to their frequency and duration (Bender 1956) His finding is suggestive in speculating on the mechanism of "optokinetic nystagmus firing In any case, the present result is, we feel, valuable because this phenomenon has not been studied in connection with the activity of the cervical proprioceptors.

(5) Mechanism of optic proprioceptive coordination in rabbits from the standpoint of fiber connections of the central nervous system

From our experiments, it seems that the brain stem reticular formation is the most important in the mechanism of integration of impulses from the optic organ and the cervical proprioceptors. We would like here to discuss whether this idea is justifiable from the neuro-anatomical point of view

Recently Fukuda proposed a scheme concerning the optokinetic reflex arc (Fukuda 1967). According to his scheme neural pathways related to the optokinetic eye reflexes involve the following elements, arranged in the following way the retina→the optic nerves→the superior colliculus→the tectocerebellar tract→the cerebellar cortex→the cerebellar nuclei particularly the fastigal nucleus→the vestibular nuclei→the MLF→the oculomotor nuclei→the oculomotor nerves→the eye muscles. Morimoto stressed the importance of the vestibular nuclei in the formation of optokinetic nystagmus, since he found that optokinetic nystagmus could not be induced in a rabbit with bilaterally damaged vestibular nuclei although this nystagmus could be induced slightly about a week after the operation (Morimoto 1955) However there is an uncertain point in Fukuda's scheme because Tashiro studying fiber connections between the superior colliculus and the cerebellum in cats, stated that there were no definite connections between these two parts of the brain (Tashiro 1940) Niimi suggested the possibility of connections between the superior colliculus and the vestibular nuclei through the pontine nucleus, the cerebellar cortex and the cerebellar nucleus (Niimi, 1970) But there is still controversy over his suggestion since the cerebellar nucleus involved in this reflex arc belongs to one developed at a late stage of phylogenesis, while the vestibular nuclei belong to one developed at an earlier stage and it is generally accepted that fiber connections in the central nervous system are formed between neural elements developed at the same stage of phylogenesis.

The other possible neural pathways may involve the following elements, arranged in the following way the retina→the optic nerves→the superior colliculus→tectoreticular fibers→the brain stem reticular formation→the MLF→the oculomotor nuclei→the oculomotor nerves→the eye muscles. Rasmussen found the presence of crossed nerve fibers connecting the superior colliculus to the brain stem reticular formation (Rasmussen, 1936). Tashiro also found that there are two types of tectoreticular fibers, i e. crossed and uncrossed (Tashiro, 1939) Pearce demonstrated that the terminal region of the tectoreticular fibers from the superior colliculus is in the medial part of the pontine and medullary reticular formation including the nuclei reticularis gigantocellularis, pontis caudalis and oralis. While these connections are mainly contralateral, fibers to the midbrain reticular formation are chiefly homolateral (Pearce, 1956).

These findings suggest that optokinetic nystagmus may be mainly formed in the brain stem reticular formation and the superior colliculus independently of the cerebellum and the vestibular nuclei

The spinoreticular tract seems the most important tract connecting the cervical proprioceptors with the central nervous system and particularly the brain stem reticular formation, because this tract originates abundantly in the cervical cord and ascends along the lateral fascicle and the anterior column and terminates in the reticular formation both of the pons and the medulla oblongata (Brodal 1957 Nauta & Kuypers, 1958 Bowsher 1965). Some fibers of this tract ascend directly to the midbrain reticular

NEUROTOLOGICAL STUDIES ON THE ROLE OF THE SYMPATHETIC NERVOUS SYSTEM IN THE FORMATION OF TRAUMATIC VERTIGO OF CERVICAL ORIGIN

Manabu Hinoki and Hiroshi Niki

From the Department of Otolaryngology, School of Medicine, Tokushima University, Tokushima, Japan

Abstract. To test the validity of the hypothesis that irritation of the cervical sympathetic nerves is a cause of hypertonicity of the cervical soft supporting tissues, especially the deep nuchal muscles, and that this hypertonicity is a cause of traumatic vertigo of cervical origin, we examined 44 vertigo cases with whiplash injury by testing equilibrium function and EMG discharges from the neck before and after administration of drugs affecting the sympathetic receptors. The results obtained were as follows.

1. Administration of iso-proterenol (beta-receptor stimulant) caused a significant increase in the EMG's from the injured neck muscles, in parallel with increased impairment of the righting reflex. The blindfolded vertical writing test showed the appearance or intensification of ataxia or deviation in writing when this drug was given. In contrast, administration of propranolol (beta-receptor depressor) had the opposite effects on the EMG's, the righting reflex and blindfolded vertical writing. Furthermore, the resulting changes in the EMG's and equilibrium functions were parallel with alterations in subjects' complaints, i.e., increase or decrease in neck pain and vertigo.

2. Administration of drugs affecting the alpha receptors, such as noradrenaline (alpha-receptor stimulant) and phentolamine (alpha-receptor depressor) had no appreciable effect on the EMG's, equilibrium function or the subjects' complaints.

These results show that in vertigo due to whiplash injury hypertonicity of the cervical erector muscles can be induced sympathetically and that this hypertonicity is based on over-excitement of beta receptors in the injured neck muscles, which results in vertigo of cervical origin.

Since the work of Barré it has been widely believed that irritation of the cervical sympathetic nerve is a main cause of vertigo of cervical origin. According to this theory irritation of the cervical sympathetic nerve may result in circulatory disorders either of the vertebral artery or of the internal auditory artery and these disorders are major factors in producing vertigo of cervical origin (Barré, 1926; Lieou, 1928; Maspetiol, 1960). This theory is supported clinically and experimentally and we have taken it into consideration in assessing the mechanism of traumatic vertigo of cervical origin, such as whiplash injury. However, we feel that the importance of the sympathetic nervous system in producing vertigo due to whiplash injury is also related to its effect in producing hypertonicity of the cervical soft supporting tissues and especially the erector muscles of this region for the following reasons. Many traumatic cases with Barré's syndrome which we have examined showed both cervical pain, suggesting hypertonicity of the cervical soft supporting tissues, and abnormal responses of the autonomic nervous system. Furthermore, improvement or aggravation of autonomic nervous syndromes during treatment was parallel with changes in the extent of nuchal pain. For example, among 17 of our clinical cases in which pain in the neck decreased or disappeared during the observation period, 13 cases (76.4%) showed improvement of autonomic syndromes, whereas all the 9 cases in which pain in the neck increased showed aggravation of autonomic syndromes. We also found a close correlation between vertigo and neck pain in cases with whiplash injury. For instance, among 17 of our vertigo cases in which pain in the neck disappeared or decreased during the observation period, 13 cases (76.4%) showed reduction of vertigo. Whereas all the 9 cases in which pain in the neck increased showed aggravation of

tion of each of these drugs. Then, we observed the relationship between the resulting changes in equilibrium function and those in the EMG's from the neck.

2. *Subjects examined*

Forty-four cases with whiplash injury aged 15 to 50 were examined by the equilibrium tests mentioned above. The period between the time of the accident and the time of examination varied from as little as one month to as much as 3 years. All cases in which the head had struck a solid object were omitted. So the cases tested had no serious brain symptoms.

3. *Results on vertigo cases with whiplash injury using iso-proterenol*

(i) Representative case. A 31 year-old woman who had sustained whiplash injury 8 months before. After her accident this woman developed swaying of the body associated with pain of the right side of the neck and headache. X Rays of the neck showed no abnormal findings except a slight incongruence of c_5 of the cervical vertebrae. Fig. 1 shows registrograms of movements of the head (bottom) and the EMG's from the neck (upper two rows). After intramuscular injection of iso-proterenol this woman complained that pain in the neck and swaying of the body became much worse. Fig. 1 shows that this was endorsed by a significant increase in abnormal EMG discharges from the neck and swaying of the body (head). It is worth noting that the EMG's from the right of the neck were more abnormal than those from the left before the injection, and that after the injection the EMG's from the right of the neck became even more abnormal with burst-like muscular discharges.

Fig. 2 shows the blindfolded vertical writing tests of the same subject before and after injection of iso-proterenol. Ten minutes after the injection, her writing became markedly ataxic. This supports the subject's complaint of increased vertigo.

(ii) Results on 13 cases with whiplash injury. In 8 of the 13 cases with whiplash injury tested, abnormal EMG's from the neck and disturbances of the righting reflex apparently increased when iso-proterenol was given. Two cases did not show any significant increase in the EMG's, but showed slight aggravation of the righting reflex. In the other 3 neither increase in the EMG's nor in disturbances of the righting reflex was seen.

In the same group 8 cases showed the appearance or intensification of ataxia (particularly tremor-like movements) in the blindfolded vertical writing test. Two cases did not show any ataxia, but showed a significant increase in deviation in writing. In the other 3 no significant changes were observed.

The changes evoked in these cases by drug injection were closely related with complaints of increase in symptoms, such as nuchal pain and vertigo.

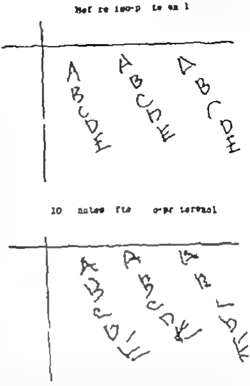

Fig. 2. The blindfolded vertical writing tests of 31-year old woman with whiplash injury before and after administration of iso-proterenol. After administration of this drug, writing became markedly ataxic. This supported the subject's complaints of increased vertigo.

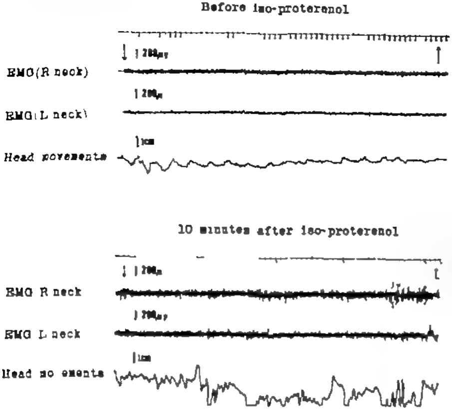

Fig 1 EMG s from the neck and registrograms of movements of the head of a 31 year-old woman with whiplash injury in the position for Mann's test, before and after administration of iso-proterenol. When the drug was injected intramuscularly this subject complained of increased pain in the neck and unsteadiness. This was endorsed by significant increase in abnormal EMG discharges from the neck and swaying of the body (head).

vertigo These results suggest that irritation of the cervical sympathetic nerves can induce hyper tonicity of the erector muscles of this region This hypertonicity may also be an etiological factor in causing vertigo due to whiplash injury

The present work was undertaken to clarify the validity of this idea.

EXPERIMENTAL

1 *Equilibrium tests after treatment with drugs affecting the sympathetic receptors*

Principle and method To test the validity of the hypothesis that irritation of the sympathetic nervous system is a cause of hypertonicity of the cervical soft supporting tissues, which results in vertigo of cervical origin it is necessary to see whether changes in the activity of the sympa thetic nervous system can cause decrease or in crease in the tonus of the cervical soft supporting tissues and especially the erector muscles of this region and whether the changes in the tonus of the cervical soft supporting tissues thus evoked are parallel with those of vertigo One method used for examining the validity of this assump tion is to inject drugs affecting the sympathetic nervous system and then to study the correlation between the consequent changes in the EMG s from the neck region and those in eye and body equilibrium

Ahlquist and other workers found that there are two kinds of sympathetic receptors alpha and beta. Recent investigations revealed that various drugs can stimulate or suppress the activity of either the alpha or beta receptors (Ahlquist 1948). For instance, noradrenaline is known to stimulate the activity of alpha receptors, while phentolamine has the opposite effect on these receptors. Iso-proterenol and propranolol are known to stimulate and depress beta receptors, respectively Thus, we tested the effects of these drugs on the symptoms of vertigo cases with whiplash injury We measured changes in vertigo by examining body equilibrium in various ways, such as by testing the righting reflex (Mann s position) and the arm drift reaction (the blindfolded vertical writing test). We also took EMG records from the neck of the subjects before and 10 minutes after adminis-

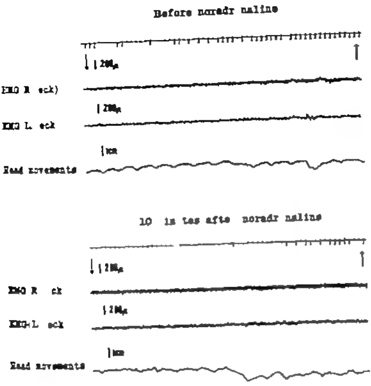

Fig. 5. EMG's from the neck and registrograms of movements of the head of 36-year-old woman with whiplash injury in the position for Mann's test, before and after administration of noradrenaline. After intramuscular injection of noradrenaline this woman reported no significant change in the pain in her neck or her sensation of swaying. This was endorsed by the lack of change in either the EMG's from the neck or registrograms of movements of the head after injection of noradrenaline.

In 10 of the 16 cases with whiplash injury tested, abnormal EMG's from the neck and disturbances of the righting reflex decreased when propranolol was given. One case showed no significant decrease in the EMG's, but improvement of the righting reflex. The other 5 showed neither decrease in the abnormal EMG's nor change in disturbances of the righting reflex.

In the same group, 6 cases, who showed ataxia and deviation in writing showed reduction in these abnormalities after this drug was given. Among 10 cases who showed only deviation in writing, 5 cases showed reduced deviation and 4 cases showed no significant change after injecting the drug. The remaining case developed slight ataxia in writing.

i. *Results on vertigo cases with whiplash injury using noradrenaline*

(i) Representative case. A 36-year-old woman who sustained whiplash injury when her car was bumped from the rear 6 months previous to examination. She was slightly dazed for about 5 minutes after the accident, but has had no memory defect since that time. She complained of pain of the right side of the neck, headache and a sensation of falling associated with the weather. X Rays of the neck showed no structural abnormality. We tested the effects of noradrenaline on this subject, and observed the resulting changes in the EMG's from the neck and in the righting reflex. Fig. 5 shows the EMG's from the neck and registrograms of movements of the head before and after injection of noradrenaline. There were no demonstrable changes either in the EMG's or in the righting reflex after injecting the drug. The blindfolded vertical writing tests of this subject in Fig. 6 show no apparent change in writing after noradrenaline was given. Furthermore, when we injected noradrenaline into this woman intramuscularly her complaints did not change. This was compatible with the results of the EMG's and the equilibrium tests mentioned above.

(ii) Results on 8 cases with whiplash injury

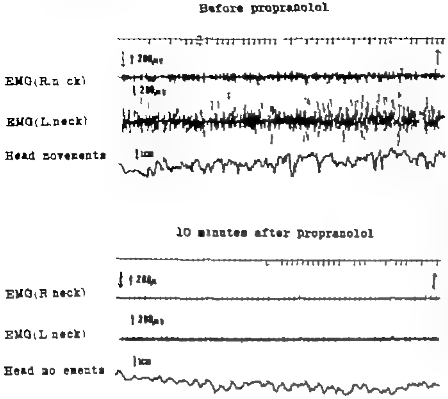

Fig 3. EMG s from the neck and registrograms of movements of the head of a 40-year-old man with whiplash injury in the position for Mann s test, before and after administration of propranolol. After intravenous injection of this drug the subject reported decreased pain in the neck and less sensation of falling. This was endorsed by marked reduction in abnormal EMG s from the neck and in swaying of the body (lower records).

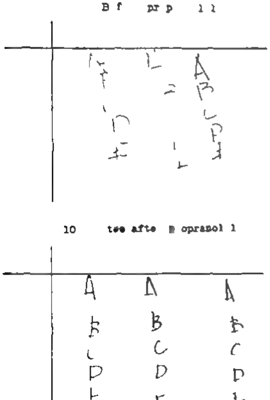

Fig 4 The blindfolded vertical writing tests of a 40-year old man with whiplash injury before and after administration of propranolol. After propranolol deviation in writing almost disappeared and ataxic writing became less. This was parallel with reduction in a sensation of falling.

4 *Results on vertigo cases with whiplash injury using propranolol*

(i) Representative case A 40-year-old man who sustained whiplash injury when his car was bumped by a vehicle 3 months previous to examination. He wad dazed for about 10 minutes after the accident and after one hour he developed pain of the left side of the neck, photophobia and a sensation of falling associated with black-out on standing up X Rays of the cervical spine revealed a slight incongruence ($c_{3,4}$) and loss of the normal cervical curve The nuchal pain and sensation of falling decreased when propranolol was given. This was endorsed by the results shown in Fig. 3 the abnormal EMG discharges from the neck decreased and swaying of the body (head) became much less. Further more, this drug effectively reduced the abnormality in muscular discharges from the left of the neck seen before the injection.

Fig. 4 shows the blindfolded vertical writing tests of the same subject before and after injection of propranolol. Deviation in writing almost disappeared and ataxic writing became significantly less. This also indicates decrease in vertigo

(ii) Results on 16 cases with whiplash injury

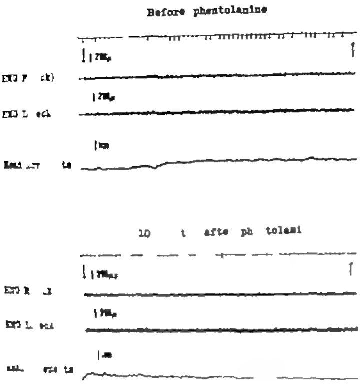

Fig. 7. EMG's from the neck and registrograms of movements of the head of a 30-year-old woman with whiplash injury in the position for Mann test, before and after administration of phentolamine. After injecting this drug intramuscularly there was no significant change in pain in the neck or in the sensation of falling. This was endorsed by the lack of change in either EMG's from the neck or registrograms of movements of the head.

tor depressor propranolol, had the opposite effects on the EMG's, the righting reflex and blindfolded vertical writing. Furthermore, the resulting changes in the EMG's and in equilibrium function caused by administration of drugs affecting the beta receptors were parallel with alterations in the subjects' complaints of neck and vertigo. In contrast to this, administra of drugs affecting the alpha-receptors caused appreciable changes in the EMG's, equili- m tests or the subjects' complaints. So, these ts show that hypertonicity of the cervical tor muscles in vertigo due to whiplash injury s not depend on the activity of alpha recep- . It depends on *over-excitement of beta* ptors in the injured skeletal muscles of the k.

owman & Raper (1967) showed that iso- terenol participates in elevation of muscle es of denervated *slowly* contracting skeletal scles through activation of beta receptors. r clinical results seem to be in agreement of ir conclusion.

This conclusion is also supported by our results on rabbits (Hinoki & Niki, 1972). To simulate the damage of the neck muscles observed in human subjects with whiplash injury 6% saline solution was injected repeatedly into the deep nuchal muscles of rabbits on one side. Iso-proterenol or noradrenaline was injected into the same site in the nuchal muscles before and after the saline, and the resulting changes in equilibrium function and tonus of the neck muscles were measured by recording eye nystagmus and the EMG simultaneously. The following results were obtained from these experiments.

(i) *After injection of iso-proterenol into the unilateral* deep nuchal muscles of normal rabbits there was no appearance of nystagmus (or abnormal eye movements) or marked increase in the EMG's from the muscles into which iso-proterenol was injected.

(ii) After about 10 injections of 6% saline solution into the unilateral deep nuchal muscles rabbits sometimes showed moderately elevated

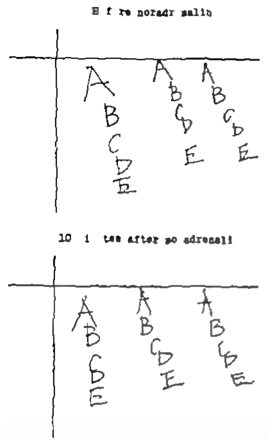

Fig 6 The blindfolded vertical writing tests of a 36-year old woman with whiplash injury before and after administration of noradrenaline. After injecting this drug complaints of pain in the neck and vertigo did not change and there was no significant change in writing.

We tested the effect of noradrenaline on 8 cases with whiplash injury using the EMG the righting reflex test and the blindfolded vertical writing test None of the cases showed any significant change in either the EMG s or the equilibrium tests.

6 *Results on vertigo cases with whiplash injury using phentolamine*

(i) Representative case A 30-year-old woman who had sustained whiplash injury one month before At the time of the accident she was aware of a cracking sound in the neck A few minutes later pain of the left side of the neck, left tinnitus and a sensation of swaying developed X Rays of the neck showed no structural abnormality except a slight incongruence of the cervical vertebrae ($c_{4,5}$). When we injected phentolamine into this woman intramuscularly her complaints did not change. This was endorsed by the results shown in Figs. 7 and 8 That is, the abnormal EMG s from the neck and disturbances of the righting reflex showed no demonstrable changes when this drug was given (Fig. 7) The blindfolded vertical writing test of this subject showed no apparent change in writing after phentolamine was given (Fig. 8).

(ii) Results on 7 cases with whiplash injury We tested the effect of phentolamine on 7 cases with whiplash injury by examining the EMG s and by the equilibrium tests mentioned above. None of the cases tested showed any significant change in either the EMG s or the equilibrium tests.

COMMENT

1 *Remarks on sympathetic induction of hypertonicity of the neck muscles and its contribution to development of vertigo based on clinical and experimental observations*

Many workers have reported that cervical vertigo is due essentially to circulatory disorders of the vertebral artery or of the internal auditory artery originating from irritation of the posterior cervical sympathetic nerve (Barrè, 1926 Lieou 1928 Maspetiol, 1960) However in cases of whiplash injury we often found that there was a close association between complaints, such as neck pain, suggesting hypertonicity of the cervical soft supporting tissues, and various autonomic syndromes and vertigo So we wondered whether hyperstimulation of the autonomic nerves, especially the cervical sympathetic nerve brings about hypertonicity of the cervical muscles and promotes the appearance or intensification of vertigo This idea was supported by the results mentioned above That is, administration of beta receptor stimulant, iso-proterenol, caused an increase in abnormal EMG discharges from the neck muscles in parallel with increased impairment of the righting reflex Similar results were obtained by the blindfolded vertical writing test. That is, when this drug was given ataxia or deviation in writing appeared or was intensified. Whereas administration of the beta recep-

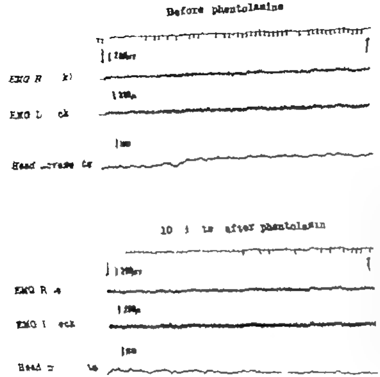

Fig. 7 EMG's from the neck and registrograms of movements of the head of a 30-year-old woman with whiplash injury in the position for Mann's test, before and after administration of phentolamine. After injecting this drug intramuscularly there was no significant change in pain in the neck or in the sensation of falling. This was endorsed by the lack of change in either EMG's from the neck or registrograms of movements of the head.

tor depressor propranolol, had the opposite effects on the EMG's, the righting reflex and blindfolded vertical writing. Furthermore, the *resulting changes in the EMG's and in equilibrium* function caused by administration of drugs affecting the beta receptors were parallel with alterations in the subjects' complaints of neck pain and vertigo. In contrast to this, administration of drugs affecting the alpha-receptors caused no appreciable changes in the EMG's, equilibrium tests or the subjects' complaints. So, these results show that hypertonicity of the cervical erector muscles in vertigo due to whiplash injury does not depend on the activity of alpha receptors. It depends on over-excitement of beta receptors in the injured skeletal muscles of the neck.

Bowman & Raper (1967) showed that isoproterenol participates in elevation of muscle tonus of denervated slowly contracting skeletal muscles through activation of beta receptors. Our clinical results seem to be in agreement of their conclusion.

This conclusion is also supported by our results on rabbits (Hinoki & Niki, 1972). To simulate the damage of the neck muscles observed *in human subjects with whiplash injury* 6% saline solution was injected repeatedly into the deep nuchal muscles of rabbits on one side. Iso-proterenol or noradrenaline was injected into the same site in the nuchal muscles before and *after the saline, and the resulting changes in* equilibrium function and tonus of the neck muscles were measured by recording eye nystagmus and the EMG simultaneously. The following results were obtained from these experiments.

(i) After injection of iso-proterenol into the unilateral deep nuchal muscles of normal rabbits there was no appearance of *nystagmus* (or abnormal eye movements) or marked increase in *the EMG's from the muscles* into which iso-proterenol was injected.

(ii) After about 10 injections of 6% saline solution into the unilateral deep nuchal muscles rabbits sometimes showed moderately elevated

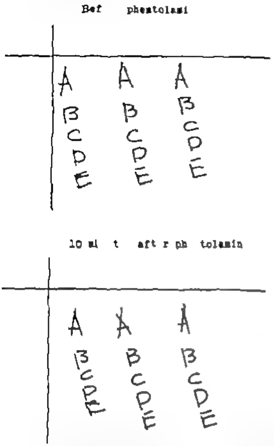

Fig 8 The blindfolded vertical writing tests of a 30-year-old woman with whiplash injury before and after administration of phentolamine. After this drug was injected intramuscularly there was no significant change in complaints of pain in the neck and vertigo. This was endorsed by the lack of change in deviation in writing.

EMG discharges from the neck muscles affected by saline and only slight spontaneous nystagmus. When iso-proterenol was injected into the same site in these muscles, the animals tended to show a marked increase in the EMG s from these muscles and intensification of pre-existing spontaneous nystagmus.

Injection of noradrenaline into the same muscles caused no increase in nystagmus or in muscular discharges.

These results also support our previous idea on vertigo of traumatized patients i.e. over excitement of beta receptors in the injured neck muscles, especially the deep nuchal muscles, can cause hypertonicity of these muscles and this hypertonicity results in vertigo of cervical origin However there has been much discussion as to whether innervation of the sympathetic nervous system affects the tonus of the skeletal muscl exists. Thus, to confirm our idea more definitel we have first to examine the reports on th problem and then to obtain some evidence on th morphological relationship between the symp thetic nerves and muscle fibers, especially th muscle spindles of the neck muscles.

2. *Reports on the effect of sympathetic innervation on the tonus of skeletal muscles*

Fulton detected a decrease of muscle tonus afte sympathectomy (Fulton, 1928). Popa & Pop also suggested that if the sympathetic pre ganglionic fibers are transected, prolonge muscle hypotonia may result (Popa & Popa 1931). Kuntz and Kerper found that the muscle of the wing of birds are not atonic after sectio of the dorsal roots of the brachial plexus. How ever they become atonic after section of bot the dorsal roots of the brachial plexus and th cervical sympathetic trunk (Kuntz & Kerper 1926) These findings are very similar to those reported by Hunter (Hunter 1924). Recently Hunt reported that primary sympathetic actions not related to changes in blood flow can be mediated directly to the muscle spindle, presumably through postganglionic sympathetic nerve fibers in the spindle (Hunt, 1960) From this he stressed the possibility of a significant direct i e non-humoral, contribution of the sympathetic nervous system to motor integra tion via "sympathetic bias" on the muscle spindle, in addition to the "gamma bias"

These findings suggest that there may be a functional relationship between the sympathetic nerves and the somatic proprioceptive reflex arcs in maintenance of muscle tonus. However there is still controversy on this subject. So we must discuss this problem further by examining recent works using new technics before we mention our results. Barker first reported the existence of intrafusal sympathetic innervation, but has recently retracted his view (Barker 1967) Boyd also discredited this possibility (Boyd 1962). Thus, at present this possibility may be neglected. Recently Santini and his group have studied this subject. They made electron microscopic

studies on the tenuissimi and lumbrical muscles of 4 cats, one of which was treated with 5-hydroxydopamine (5-HDA). They found that there are bundles of thin axons (less than 0.5 μ) in the capsular spindle and in the extracapsular polar regions. Following 5-HDA treatment some of these fibers were found to contain large dense vesicles (80 nm) not seen in the other axons of the bundle in semi-serial sections. They also found that after 5-HDA treatment these thin axons with large dense vesicles were seen in bundles which included larger unmyelinated axons, presumably of the gamma type, which are normally devoid of large dense vesicles (Santini & Ibata, 1971). These findings seem to indicate that there is a morphological relationship between the sympathetic postganglionic fibers and the muscle spindles.

3. *Our observations on the morphological relationship between the sympathetic nerves and muscle fibers, particularly the muscle spindles*

To obtain further evidence on this subject, we and Dr Daikoku recently made electron microscopic studies on the deep nuchal muscles of rabbits (Niki et al., 1973). Our results were as follows.

Sensory and motor nerve endings were seen on the surface of intrafusal muscle fibers of the deep nuchal muscles of rabbits, but no indications of sympathetic nerve endings were found. However as shown in Fig. 9 in the perimysium of the muscle spindle, apart from myelinated nerve fibers, unmyelinated nerve fibers of 0.3–1.5 μ diameter could be detected. Granular vesicles in these nerve fibers were 900–1200 Å in diameter. In normal rabbits, these nerve fibers rarely contain granules and are difficult to distinguish. In the muscle spindle cavity unmyelinated nerve fibers could also be observed. In normal rabbits these nerve fibers contain a very few granules and are difficult to distinguish. However as shown in Fig. 10, unmyelinated nerve fibers in the muscle spindle cavity of the injured neck muscles of rabbits with spontaneous nystagmus contain large granules and are more easily detectable. Furthermore, it is, we feel, interesting in relation to innervation of gamma fibers on muscle tonus that these unmyelinated nerve fibers were always detected near to motor nerve endings of intrafusal muscle fibers. There seems to be a certain similarity in nature between the core vesicles described by Santini and Ibata and those described here. Thus, the present findings suggest that there is a morphological relationship between sympathetic nerve fibers and the muscle spindles. Our findings also suggest that there is hyperexcitation of the sympathetic nerve in the muscle spindle of neck muscles after saline injection, because Santini and Ibata showed that the granules in the thin unmyelinated nerve fibers in the capsular spindle are manifested after treatment with 5-HDA (Santini & Ibata, 1971). Of course, further investigations using other examinations, such as formaldehyde-induced fluoresence (Falk–Hillarp method), are necessary to prove definitely whether postganglionic sympathetic nerve fibers connect with the muscle spindles of the neck muscles of rabbits. Furthermore, even if the present findings show that postganglionic sympathetic nerve fibers connect with the muscle spindles, they do not give direct proof that these sympathetic nerve fibers can play a similar role to beta receptors in elevation of muscle tonus. However from our morphological findings described above and our clinical and experimental observations on the effect of drugs acting on the sympathetic receptors, it seems probable that over-excitement of the cervical sympathetic nerves related to the beta receptors in the neck muscles causes abnormal increase in the activity of the proprioceptors of these muscles. Thus, hypertonicity of the neck muscles is produced sympathetically and this in turn results in vertigo of cervical origin.

4. *Neural mechanism of cervical vertigo in relation to sympathetically induced hypertonicity of the neck muscles*

The question then arises of how the hypertonicity thus evoked can induce vertigo of cervical origin. We have been studying central mechanism

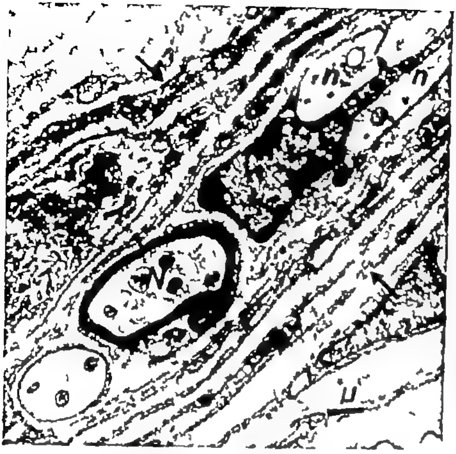

Fig 9 Perimysium of the muscle spindle of the deep nuchal muscles of a normal rabbit. In the perimysium, apart from a myelinated nerve fiber (*N*), unmyelinated nerve fibers of 0.5–1.5 μ diameter can be seen. These nerve fibers contain granular vesicles of 900–1200 Å diameter (*n*). The arrows indicate the borders of the perimysium.

Fig 10 Muscle spindle cavity of the injured deep nuchal muscles of a rabbit with spontaneous nystagmus. An unmyelinated nerve fiber contains large granules, seen in the area enclosed in a square in the upper part of this figure. The nerve fiber with these granules is far more easily detectable in the injured deep nuchal muscles of rabbits with spontaneous nystagmus than in those of normal rabbits. The inserted figure shows the granules at higher magnification. *N* myelinated nerve fiber *Nuc* nucleus *Nm* motor nerve endings.

of vertigo due to whiplash injury since 1967. Our opinion on this mechanism has been that there is a close relationship between the tonus of the deep nuchal muscles and the activity of the brain stem and the cerebellum, and that hypertonicity of the deep nuchal muscles and dysfunction of these parts of the brain have a trigger-and-target relationship in bringing about vertigo of cervical origin. However, we proposed this idea from the standpoint of the gamma system (Hinoki et al., 1971). It remained to be determined whether this idea could be applied to interpretation of the mechanism of vertigo due to hypertonicity of the neck muscles by the sympathetic nerves. We tested this in rabbits (Hinoki & Niki, 1972). The effects of drugs and optokinetic stimulation on the EEG, EMG and ENG of the rabbits were examined before and after repeated injections of 6 % saline solution into the deep nuchal muscles. The results obtained were as follows.

(i) A normal rabbit showed only slight increase in the EMG's from the deep nuchal muscles and fairly good development of optokinetic nystagmus when iso-proterenol was injected into these neck muscles. In parallel with this, the EEG's from various parts of the brain, such as the hippocampus, the midbrain reticular formation and the neo-cortex, showed a fairly good arousal reaction.

(ii) However, in the same rabbit after repeated injections of 6 % saline solution into the deep nuchal muscles, a marked increase in the EMG discharges developed when iso-proterenol was injected. In parallel with this, there was little evidence of optokinetic nystagmus. The EEG's showed that the arousal reaction was inhibited.

These results showed that sympathetically induced hypertonicity of the deep nuchal muscles can cause disorders of the brain stem reticular formation. Its effects on the cerebellum are still unknown.

From these clinical and experimental observations, the mechanism of sympathetically induced vertigo of cervical origin seems to be as follows. After whiplash injury sympathetic nerves related to the beta receptors in the injured neck muscles may become over-excited, and thus markedly enhances the activity of the proprioceptors of these muscles. Thus, abnormal centripetal impulses from these receptors may ascend along centripetal paths, such as the spinoreticular tract, and reach the brain stem and the hypothalamus causing dysfunction of these parts of the brain. This dysfunction may be projected to the eyes, the trunk and the limbs through descending paths, such as the reticulospinal tract and the MLF causing disability or ataxia of these organs. Thus, vertigo is possibly induced by this ataxia or disability. Of course, hypertonicity of the deep nuchal muscles may also have some effect on the activity of the cerebellum, which is one of the important centers of the proprioceptive reflexes. Naturally dysfunction of this part of the brain participates in producing vertigo, in close collaboration with the brain stem.

In addition to these neural mechanisms, we should also take the following mechanism into consideration in assessing vertigo of this type. That is, the dysfunction of the brain stem and the hypothalamus mentioned above may be conveyed to the neck muscles through centrifugal (descending) sympathetic paths, such as Schutz's longitudinal dorsal fascicle and the cervical sympathetic nerves. Thus, tonus of these muscles is increased and this in turn, causes vertigo of cervical origin.

ACKNOWLEDGEMENTS

The authors are greatly indebted to Prof. K. Niimi (Dept. of Anatomy, Okayama Univ.) for valuable advice on fiber connections in the central nervous system and Prof. S. Daikoku (Dept. of Anatomy, Tokushima Univ.) for collaboration in electron microscopic studies on skeletal muscle fibers. The assistance and helpful discussions of other members of the ENT Department of Tokushima University are gratefully acknowledged.

LUMBOMUSCULAR PROPRIOCEPTIVE REFLEXES IN BODY EQUILIBRIUM

Manabu Hinoki and Nobuya Ushio

From the Department of Otolaryngology, School of Medicine, Tokushima University, Tokushima, Japan

Abstract. To evaluate the role of reflexes related to the lumbar proprioceptors in maintenance of body equilibrium, changes in equilibrium function of the eyes and body were observed after unilateral procainization of the lumbar erector muscles. Observations were made on normal subjects and vertigo cases with lumbar pain after whiplash injury using various equilibrium tests. The results obtained were as follows:

(1) On unilateral procainization of the lumbar erector muscles of normal subjects, eye nystagmus and disturbances of the righting reflex developed. Simultaneously changes in drift reactions of the lower limbs were detected by the stepping test. Namely, in many of the subjects examined the direction of stepping deviation became quite different from that before procainization, and stepping after procainization tended to show slight or moderate ataxic features, associated with sensation of unsteadiness.

(2) When procaine was injected unilaterally into tender spots at the lumbar erector muscles of traumatic vertigo cases, spontaneous eye nystagmus and disturbances of the righting reflex decreased. Simultaneously significant changes in the drift reactions of the lower limbs were observed in many of the cases examined. Namely, the direction of deviation became the opposite of that before procainization and ataxia in walking almost disappeared with reduction in vertigo.

The following conclusions were drawn from these findings.

(1) The effects of procaine on equilibrium of normal subjects are in sharp contrast to its effects on equilibrium in traumatic vertigo cases. Findings in the former might be due to increased imbalance between the activities of the right and left lumbar proprioceptors, while those in the latter might be due to decreased imbalance between the two.

(2) These findings support the view that from the standpoint of body equilibrium, there are two phases of the proprioceptive reflex, and that Fukuda's concept of two phases of the labyrinthine reflex, i.e. a stage of disturbance and a stage of coordination, can be applied to interpretation of the proprioceptive reflex of lumbar origin.

Using newly devised vestibular tests, i.e., the blindfolded vertical writing test and the stepping test Fukuda showed that eye and body reflexes induced by labyrinthine stimulations, such as rotation and calorization, vary significantly according to the magnitude or intensity of labyrinthine stimuli given and the ability of subjects to react to these stimuli. Thus, he introduced the new idea that there are two phases of the labyrinthine reflex from the standpoint of body equilibrium, i.e., the stage of disturbance and the stage of coordination (Fukuda, 1958). The former stage is produced by intense labyrinthine stimulation, which causes a marked vestibular imbalance, and includes disturbances of bodily equilibrium reflexes as well as experimental eye nystagmus, an important sign of *disturbed labyrinthine function*. At this stage labyrinthine reflexes overwhelm the power of the will and consequently disrupt normal regulation of the entire body musculature by the will, which results in ataxia of the eyes and body. *Thus, vertigo of labyrinthine origin is produced.* The stage of coordination was described vaguely under the name of "latent nystagmus" or *Nystagmusbereitschaft*. *This stage is induced* by mild or adequate labyrinthine stimulation, which causes a slight vestibular imbalance, and includes neither disturbances *of the righting* reflex nor experimental eye nystagmus. *However* at this stage there is still a drift phenomenon of the limbs, the direction of which is the same as that of the rapid component of *nystagmus which would be elicited if stronger labyrinthine stimulation were applied.* Furthermore, these *drift phenomena do not* show any ataxic features. Based on these findings, Fukuda pointed out that at this stage the vestibular labyrinth acts to *help the will in regulating* the entire body muscu-

Fällen die Gleichgewichtsfunktion und die EMG-Entladung von Nackenmuskeln vor und nach der Injektion der die Sympathikus-Rezeptoren beeinflussenden Substanz gemessen.

Folgende Resultate wurden erzielt.

1) Die Injektion von Iso-Proterenol (Beta Rezeptor stimulierende Substanz) verursachte sowohl die Verstärkung der Störung des Stellreflexes als auch eine bedeutende Zunahme der EMG-Entladungen verletzter Nackenmuskeln. Beim Vertikalschreibversuch (Fukuda) wurde das Auftreten oder die Zunahme der Ataxie und des Abweichens der Schriftzeichen bemerkt, während die Injektion von Propranolol (Beta-Rezeptor unterdrückende Substanz) die EMG-Entladungen, den Stellreflex und das Vertikalschreiben entgegengesetzt beeinflusste. Ausser dem verlief die in EMG und in der Gleichgewichtsfunktion eingetretene Veränderung mit der der Beschwerde der Versuchsperson, d. h., mit der Änderung des Nackenschmerzes und des Schwindels, parallel.

2) Die Alpha Rezeptor beeinflussende Substanz, z. B. Noradrenalin (Alpha-Rezeptor stimulierende Substanz) oder Phentolamin (Alpha Rezeptor unterdrückende Substanz) hatte keine bemerkenswerte Wirkung auf EMG und die Gleichgewichtsfunktion oder auf die Beschwerde der Versuchsperson.

Diese Ergebnisse zeigen bei einem durch das Schleudertrauma verursachten Schwindel, dass die Hypertonie der Nackenmuskeln sympathisch hervorgerufen wird, und dass diese Hypertonie, die die Ursache des von dem Nacken ausgehenden Schwindels ist, in der Überreizbarkeit von Beta Rezeptoren der verletzten Nackenmuskeln ihren Grund hat.

can be temporarily blocked by direct procainization of the muscle (Walshe, 1924, Shimazu, 1959). Therefore, in this series of examinations we procainized the lumbar erector muscles directly and carried out various kinds of equilibrium tests before and after procainization. Preliminary studies on the effect of procaine on the EMG showed that the proprioceptors in the lumbar erector muscles were blocked most effectively after 10 minutes, and that blocking lasted for about 60 minutes. Accordingly equilibrium examinations were started 10 minutes after procaine injection. A needle was inserted into the lumbar erector muscles on one side at the level of $L_4 \sim L_5$ to a depth of 4 cm and 7.5–10.0 ml of procaine were injected. In normal subjects procaine was injected into the right lumbar erector muscles, while in traumatized patients the injection was given on the side on which lumbago existed or was greatest.

3. *Equilibrium Test Used*

All the subjects were examined by equilibrium tests and by routine neurological examinations and hearing tests. However this paper mainly reports results of equilibrium tests, i.e., tests of the righting reflex, a test for the drift phenomenon of the lower limbs and a test for spontaneous nystagmus. The righting reflex was examined using Mann's test and "the dynamic righting reflex test" (Ushio, 1970). The latter test was specially devised to detect disturbances of the righting reflex due to dysfunction of the lumbar proprioceptors. In this test the subject is asked to change from the upright position to the right lateral position (see *a*, *b* in Fig. 1), from the right lateral position to the upright position (see *c d* in Fig. 1), from the upright position to the left lateral position (see *a b* in Fig. 1) and from the left lateral position to the upright position (see *c d*' in Fig. 1), and to maintain each of the positions for about 5 seconds. The right and left lateral positions are those in which the subject's trunk is bent at an angle of about 30° in the pelvis. Usually the subject keeps his eyes open and the test is repeated 5 times. Changes in righting function are observed by recording head

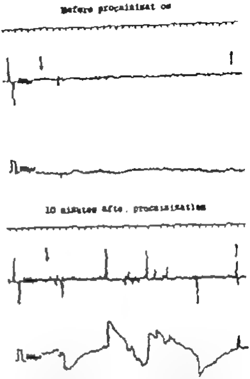

Fig. 2. ENG's of normal 20-year-old man in Mann position with the eyes closed, before and after procainization. After procainization he showed horizontal nystagmus of small and medium amplitude, with jerks to the right and left.

movements using a strain-gage-type instrument. The drift phenomenon of the lower limbs was tested by Fukuda's stepping test (Fukuda, 1958). The test for spontaneous nystagmus was carried out in Mann's position with the subject's eyes open and closed, recording the ENG.

4. *Effects of Procainization of the Lumbar Erector Muscles of Normal Subjects and Traumatized Patients*

1. *Results on normal subjects*

(1) *Representative cases.* Case 1. A normal 20-year-old man. Procaine was injected into the right lumbar erector muscles. After procainization he did not develop vertigo when he stood still with his eyes open or show demonstrable distrubances of the righting reflex in Mann's test. However the dynamic righting reflex test revealed a significant swaying of the body

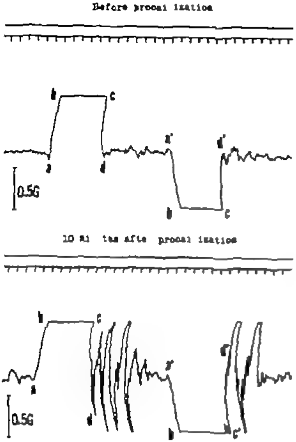

Fig 1 Head movements of a normal 20-year-old man in the dynamic righting reflex test, before and after unilateral procainization of the lumbar erector muscles. *After procainization swaying of the body (head) developed*, associated with a sensation of falling, particularly on changing to the upright position from the right and left lateral positions.

lature and consequently to promote static and dynamic equilibrium in human subjects. This concept was found to be useful in analyzing the characteristics of aural vertigo For instance, Hinoki found that the labyrinthine reflexes during the attack period of Ménière s disease correspond to those in the stage of disturbance, while the labyrinthine reflexes in the interval are very similar to those in the stage of coordination (Hinoki 1959) These findings indicate that Fukuda s concept is available in understanding not only the physiology of the vestibular labyrinth, but also vertigo induced by this organ.

The question arises of whether this concept holds in analysis of other kinds of vertigo or disequilibrium. There is some evidence that traumatic cases with vertigo and neck pain often show disequilibrium of the eye and body such as spontaneous eye nystagmus, disturbances of the righting reflex and drift reactions of the limbs with ataxic features In these cases, amelioration of vertigo and neck pain tends to be accompanied by a significant reduction in disturbances of the righting reflex and disappearance or decrease in spontaneous eye nystagmus. In parallel with this, drift phenomena of the limbs become opposite in direction and *ataxic features are reduced or abolished Similar* findings were sometimes observed in cases with whiplash injury who showed vertigo and lumbar *pain. So we wondered if Fukuda s concept could* also be applied in analyzing the characteristics of vertigo of proprioceptive origin

The present work on normal subjects and traumatized patients with vertigo of lumbar origin was to test this possibility

EXPERIMENTAL

1 Subjects Examined

In all 21 normal subjects aged 20 to 30 and 22 subjects with whiplash injury aged 20 to 46 were examined using the various equilibrium tests described below The cases with whiplash injury did not include cases in which the head had struck a solid object So none of them showed serious brain damage. However all of them showed vertigo (mostly non-rotatory) and unilateral or predominantly unilateral lumbago

2. Method of Procaini-ation of the Lumbar Erector Muscles

It is widely believed that the muscle spindles control the tonus of the skeletal muscles. Recent investigations showed that the activity of the muscle spindles is governed by fine efferent fibers, the gamma fibers. According to Matthews & Rushworth, these nerve fibers have low porcaine tolerance and their activity is markedly disturbed by procaine at a time before the activities of the motor (alpha) and sensory nerve fibers are seriously affected (Matthews & Rushworth 1957) Furthermore it has been shown that the *activity of gamma fibers in a muscle*

9 subjects (42.9 %) showed no notable disturbances of the righting reflex.

3. Results on the stepping test. Among the 21 normal subjects examined, 13 (61.9 %), who had shown rotational deviation of the body either to the right or to the left, showed a change in direction of deviation of stepping after procainization of the right lumbar erector muscles. Six (46.1 %) of these 13 subjects also developed ataxic walking. Two subjects who showed forward displacement in the stepping test, developed backward displacement with ataxic features after procainization. The remaining 6 subjects showed no significant change in the stepping test after procainization. Furthermore, development of ataxic walking was accompanied by a sensation of falling in many of the subjects examined. With regard to the relationship between the direction of deviation caused by procainization and the side of injection of procaine the following facts were found. Eight (61.5 %) of the 13 subjects developed rotational deviation of the body to the right and 5 (38.5 %) developed it to the left.

(iii) *Correlation between development of nystagmus and changes in the righting reflex on unilateral procainization of the lumbar erector muscles.* Among 12 normal subjects who showed disturbances of the righting reflex on unilateral procainization of the lumbar erector muscles, 10 (83.3 %) developed eye nystagmus and 2 (16.7 %) developed neither nystagmus nor abnormal eye movements. Whereas among 9 normal subjects who showed no sign of disturbances of the righting reflex on procainization, 5 (55.6 %) showed nystagmus and 4 (44.4 %) showed neither nystagmus nor abnormal eye movements. That is, after procaine injection spontaneous nystagmus developed *more often* in subjects showing impairment of the righting reflex than in those who did not.

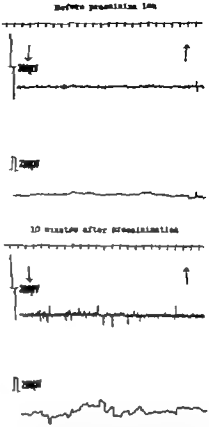

Fig. 5. ENG of normal 22-year-old man in Mann's position with the eyes closed, before and after procainization. After procainization he showed horizontal nystagmus of small amplitude, with jerks to the right and left.

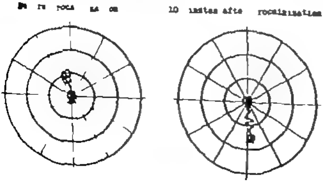

Fig. 6. Drift reaction of the lower limbs of a normal 22-year-old man in Fukuda's stepping test, before and after procainization. After procainization marked backward displacement with ataxic features developed, associated with sensation of falling backwards. The deviation in direction and way of walking were opposite before and after procainization.

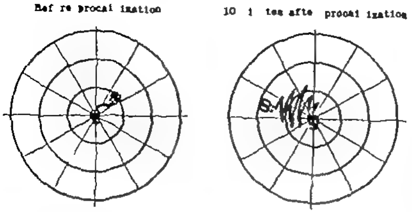

Fig 3 Drift reaction of the lower limbs of a normal 20-year-old man in Fukuda s stepping test, before and after procainization. After procainization marked deviation to the left with ataxic features developed, associated with a sensation of falling to the left. The deviation in stepping and way of walking were opposite before and after procainization.

associated with a sensation of falling, particularly when he changed to the upright position from the right or left lateral position (see *1 d'* in Fig. 1). *He also* developed horizontal nystagmus of small and medium amplitude to the right and left respectively in Mann s position with his eyes closed (Fig. 2) The stepping test showed marked deviation to the left with ataxic features, associated with a sensation of falling to the left (Fig. 3) It is worth noting that the direction of deviation and way of walking in the stepping test before and after procainization were quite different

Case 2 A normal 22 year-old man. Procaine was injected into his right lumbar erector muscles. After procainization he developed unsteadiness of the body which increased during the stepping test This was endorsed by the results of Mann s test and the stepping test. That is, as shown in Fig. 4 swaying of the body (head) was detected by Mann s test after procainization The stepping test showed backward displacement with ataxic features after procaine injection In this case also the direction of deviation and way of walking in the stepping test before and after procainization were quite different (Fig. 6) This case also developed horizontal nystagmus of small amplitude and showed nystagmus directed to the right and left (Fig. 5)

(ii) *Over-all results in all cases* 1 Results on the spontaneous nystagmus test Spontaneous nystagmus developed in 15 (71 4) of the 21 normal subjects examined after unilateral (right side) procainization of the lumbar erector muscles and in all these nystagmus was horizontal Among these 15 subjects one subject showed nystagmus to the right and 3 subjects showed nystagmus to the left The remaining 11 subjects developed nystagmus directed to both the right and left Six subjects showed neither nystagmus nor abnormal eye movements.

2 Results on the righting reflex tests After procainization disturbances of the righting reflex were observed in 12 (57 1) of the 21 normal subjects examined either by Mann s test or by the dynamic righting reflex test The remaining

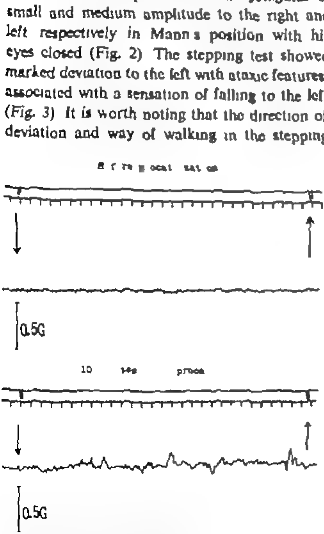

Fig 4 Head movements of a normal 22 yea -old man in Mann s test, before and after unilateral procainization of the lumbar erector muscles. After procainization significant swaying of the head developed, associated with unsteadiness of the body

9 subjects (42.9 %) showed no notable disturbances of the righting reflex.

3. Results on the stepping test. Among the 21 normal subjects examined, 13 (61.9 %), who had shown rotational deviation of the body either to the right or to the left, showed a change in direction of deviation of stepping after procainization of the right lumbar erector muscles. Six (46.1 %) of these 13 subjects also developed ataxic walking. Two subjects who showed forward displacement in the stepping test, developed backward displacement with ataxic features after procainization. The remaining 6 subjects showed no significant change in the stepping test after procainization. Furthermore, development of ataxic walking was accompanied by a sensation of falling in many of the subjects examined. With regard to the relationship between the direction of deviation caused by procainization and the side of injection of procaine the following facts were found. Eight (61.5 %) of the 13 subjects developed rotational deviation of the body to the right and 5 (38.5 %) developed it to the left.

(iii) *Correlation between development of nystagmus and changes in the righting reflex on unilateral procainization of the lumbar erector muscles.* Among 12 normal subjects who showed disturbances of the righting reflex on unilateral procainization of the lumbar erector muscles, 10 (83.3 %) developed eye nystagmus and 2 (16.7 %) developed neither nystagmus nor abnormal eye movements. Whereas among 9 normal subjects who showed no sign of disturbances of the righting reflex on procainization, 5 (55.6 %) showed nystagmus and 4 (44.4 %) showed neither nystagmus nor abnormal eye movements. That is, after procaine injection spontaneous nystagmus developed more often in subjects showing impairment of the righting reflex than in those who did not.

Fig. 6. Drift reaction of the lower limbs of a normal 22-year-old man in Fukuda stepping test, before and after procainization. After procainization marked backward displacement with ataxic features developed, associated with a sensation of falling backwards. The deviation in direction and way of walking were opposite before and after procainization.

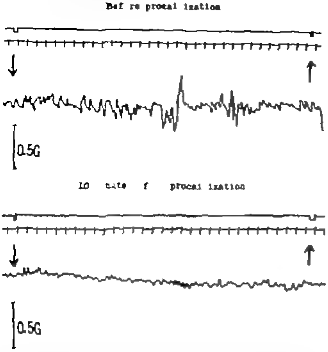

Fig 7 Head movements of a 45-year-old man with whiplash injury in Mann s test, before and after unilateral procainization of tender spots in the lumbar erector muscles. After procainization the sensation of falling and lumbar pain decreased significantly In parallel with this, disturbances of the righting reflex also decreased.

(iv) *Correlation between development of nystagmus and changes in stepping on unilateral procainization of the lumbar erector muscles* Among the 15 normal subjects who showed a change either in the direction of deviation or in the way of walking in the stepping test after procaine injection 13 (86 7 %) showed nystagmus and 2 (13 3) showed neither nystagmus nor abnormal eye movements. Whereas among 6 normal subjects who did not show any notable changes in stepping after procaine injection, 2 (33 3 %) developed nystagmus and 4 (66 7 %) developed neither nystagmus nor abnormal eye movements. That is, after procaine injection spontaneous nystagmus developed *more often* in subjects showing a change in stepping than in those who did not

2. *Results on traumatized patients*

(i) *Representative cases* Case 3 A 45-year-old man who had sustained a whiplash injury 4 months previously when his car was struck by another vehicle Immediately after the impact he did not show any notable brain symptoms, such as loss of consciousness and was not aware of any blow on the head However 24 hours after the accident he developed stiffness of the neck and nausea. Ten days after the accident pain of the waist developed associated with a sensation of falling, a dull feeling and bilateral tinnitus. These complaints are still present and are associated with the weather X Rays of the neck and waist showed no structural abnormality When procaine was injected into the right lumbar erector muscles, he reported reduction in the sensation of falling and in lumbar pain In parallel with this, disturbances of the righting reflex and spontaneous nystagmus apparently improved That is, as shown in Fig. 7 a marked decrease in swaying of the body was observed in Mann s test. He also showed a significant reduction in spontaneous nystagmus, which before procainization was marked and was directed to the right and left (Fig. 8) Moreover as shown

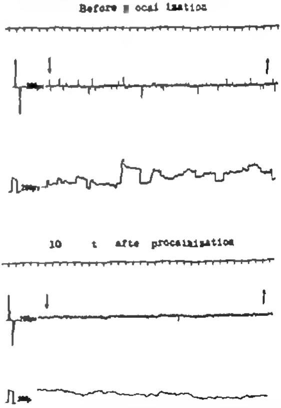

Fig 8 ENG s of a 45-year-old man with whiplash injury in Mann position with the eyes closed, before and after procainization. After procainization his spontaneous nystagmus directed to the right and left decreased significantly

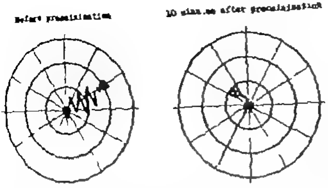

Fig. 9. Drift reaction of the lower limbs of a 45-year-old man with whiplash injury in Fukuda's stepping test, before and after procainization. After procainization deviation in stepping changed in direction and ataxic features disappeared.

in Fig. 9 the direction of deviation in the stepping test became reversed and ataxic features were lost.

Case 4. A 32 year-old man who received a whiplash injury when his car was bumped from the rear. Immediately after the impact he was dazed for a few minutes, but he was not aware of any memory defect or blow on the head. About five hours after the accident he complained of stiffness of the neck and a dull feeling. Two weeks after the accident he developed a sensation of falling and pain of the waist (particularly on the right side). X Rays of the neck and waist showed no structural abnormality. On procainization of tender spots (right side) in the lumbar erector muscles, he reported reduction in the sensation of falling and in lumbar pain. In parallel with this, impairment of the righting reflex and spontaneous nystagmus improved. That is, as shown in Fig. 10, a marked decrease in swaying of the body was observed in Mann's test. He also showed significant reduction in spontaneous nystagmus (see Fig. 11). Moreover, as shown in Fig. 12, after procainization deviation in the stepping test changed in direction to forward displacement and ataxic features were lost.

(iii) *Over-all results in all cases.* 1. Results on the spontaneous nystagmus test. Among 22 cases with whiplash injury 16 (72.7 %) showed spontaneous nystagmus before procainization. Ten (62.5 %) of the latter showed either disappearance or reduction of spontaneous nystagmus after procaine injection on the side on which lumbago existed or was greatest. The other 6 cases (37.5 %) still developed spontaneous nystagmus even after procainization.

2. *Results on the righting reflex tests.* The 22 traumatized patients all showed disturbances of the righting reflex before procainization. Among these, 17 (77.2 %) showed either disappearance or reduction in disturbances of the righting reflex after procainization, while in 5 (22.8 %) the disturbances were unchanged.

3. Results on the stepping test. Before procainization, 15 (68.2 %) of 22 cases with whiplash injury showed rotational stepping deviation either to the right or to the left, and 4 (18.2 %) showed backward displacement in stepping. The remaining 3 (13.6 %) showed neither rotational deviation nor displacement in the stepping test. Furthermore, in 19 cases rotational deviation or backward displacement in the stepping test was accompanied by ataxia in walking. On unilateral procainization of tender spots in the lumbar erector muscles, the direction of deviation of stepping of 12 (80.0 %) of the 15 cases with rotational deviation became reversed and ataxia in walking decreased. Four cases with backward displacement in the stepping test all developed forward displacement after procainization and ataxia in walking almost disappeared. The above 3 cases who showed neither rotational deviation nor backward displacement developed no significant change in the stepping test after procainization. Furthermore, reduction in ataxia in walking was parallel with decrease in either a sensation of falling or unsteadiness of the body during stepping.

With regard to the relationship between the

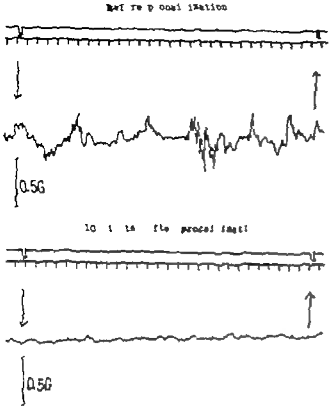

Fig 10 Head movements of a 32 year-old man with whiplash injury in Mann s test, before and after unilateral procainization of tender spots in the lumbar erector muscles. After procainization his sensation of falling back wards and lumbar pain decreased significantly and in parallel impairment of the righting reflex also decreased.

direction of deviation caused by procainization and the side of injection of procaine 8 (66 7 %) of the 12 cases with rotational stepping deviation developed deviation to the side of procainiza tion and 4 (33 3 %) to the other side

(iii) *Correlation between changes in spontaneous nystagmus and in the righting reflex after unilateral procaini-ation of tender spots in the lumbar erector muscles* Among 17 traumatized patients who showed reduction in disturbances of the righting reflex on procainization of tender spots in the unilateral lumbar erector muscles, 8 (47 1 %) showed either disappearance or decrease and 4 (23 5 %) showed no change in spontaneous nystagmus. The remaining 5 (29 4 %) did not show spontaneous nystagmus either before or after procainization Among 5 traumatized patients who did not show any demonstrable changes in disturbances of the righting reflex following procaine injection 2 (40 %) showed either disappearance or decrease in spontaneous nystagmus and 2 (40 %) showed no change in it. The remaining case (20 %) showed no spontaneous nystagmus before or after procainization That is after unilateral procainization of tender spots in the lumbar erector muscles pre-existing spontaneous nystagmus decreased more in cases showing reduction in impairment of the righting reflex than in those who did not.

(iv) *Correlation between changes in spontaneous nystagmus and in stepping after procaini-ation of tender spots in the unilateral lumbar erector muscles* Among 15 traumatized patients who showed changes in stepping, either as regard the direc tion of deviation or the way of walking after procainization 8 (53 3 %) showed reduction and 3 (20 0 %) showed no change in pre-existing nystagmus. The remaining 4 (26 7 %) showed no

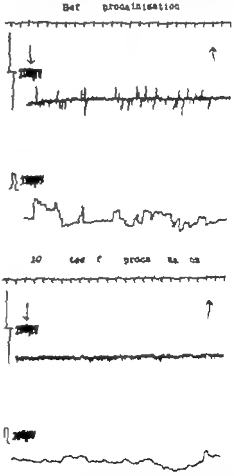

Fig 11 ENG s of a 32 year-old man with whiplash injury i Mann s position with the eyes closed, before and after procainization. After procai ization his spontaneous nystagmus directed to the right and left decreased signifi cantly

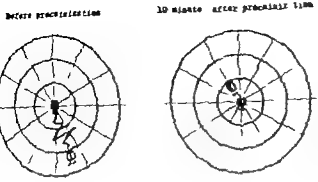

Fig. 12. Drift reaction of the lower limbs of a 31-year-old man with whiplash injury in Fukuda's stepping test, before and after procainization. After procainization the direction of deviation changed to forward displacement and ataxic gait almost disappeared.

ups of nystagmus either before or after procainization. Whereas among 7 traumatized patients who showed no demonstrable change in the stepping test after procainization, 3 (42.8%) showed reduction and 3 (42.8) showed no change in spontaneous nystagmus. The remaining case (14.3) showed no nystagmus before or after procainization. That is, after procaine injection pre-existing spontaneous nystagmus decreased more often in traumatized patients showing a change in stepping than in those who did not.

COMMENT

1. *The phases of the proprioceptive reflex of lumbar origin from the standpoint of body equilibrium, with special reference to Fukuda's "concept of two phases of the labyrinthine reflex"*

The following facts were noted from the above series of examinations

1. On procainization of the unilateral lumbar erector muscles of normal subjects, eye nystagmus and disturbances of the righting reflex developed. At the same time, changes in the drift reaction of the lower limbs were detected by the stepping test. Namely in many of the subjects examined the direction of deviation in stepping became opposite to that before procainization, and stepping after procainization tended to show slight or moderate ataxic features, associated with a sensation of falling.

2. Wh rocaine was injected unilaterally into tender spots in the lumbar erector muscles of traumatic vertigo cases, spontaneous nystagmus and disturbances of the righting reflex decreased. At the same time, significant changes in drift reaction of the lower limbs were observed in many of the cases examined. Namely the direction of deviation of stepping became the opposite of that before procainization and after procainization ataxia in stepping almost disappeared in parallel with reduction in vertigo.

Hinoki & Kurosawa have already pointed out that when procaine was injected unilaterally into either the deep nuchal muscles or the sternocleido-mastoid muscles of normal subjects, the subjects developed vertigo, as indicated by a sensation of falling, without any sign of cochlear symptoms (Hinoki & Kurosawa, 1964). This was accompanied by disturbances of the righting reflex, and also by drift reactions of the upper limbs (i.e., deviation in writing in the blindfolded vertical writing test). With the lapse of time after the injection the vertigo decreased in parallel with reduction in impairment of the righting reflex. At this stage the subjects still showed deviation in writing, but the direction of deviation was opposite to that soon after procainization. This finding is essentially similar to those obtained from the present examinations. Accordingly we may say that from the standpoint of body equilibrium there are two phases of the proprioceptive reflex. One is the reflex pattern in which disturbances of the righting reflex and spontaneous nystagmus exist, associated with drift reactions of the limbs with ataxic

features The other is that in which drift reactions of the limbs become opposite in direction and there are no signs of ataxic features. Of course, in this pattern, no impairment of the righting reflex or spontaneous nystagmus is found Based on the action of procaine on gamma fibers in the muscle, we may assume that the former reflex pattern is due to a marked functional imbalance between the right and left proprioceptors of the neck or waist while the latter is due to a slight functional imbalance between the two From the standpoint of body equilibrium, these findings are important in showing the essential similarity between the patterns of the proprioceptive reflexes of lumbar origin, just mentioned and those of labyrinthine origin initially reported by Fukuda (Fukuda 1958).

From these facts we may say that Fukuda s concept is applicable not only in understanding the characteristics of the labyrinthine reflexes, but also in analyzing those of the proprioceptive reflexes. Furthermore these findings are also helpful in explaining changes in ataxia of lumbar proprioceptive origin during treatment Without this idea, changes in drift reactions of the limbs seem too complicated to be explained uniformally although changes in disturbances of the righting reflex and in spontaneous nystagmus can be explained comparatively easily Now the various patterns of the proprioceptive reflexes related to bodily equilibrium can be explained by introducing the idea of "a stage of disturbance and a stage of coordination" initially proposed by Fukuda in relation to labyrinthine reflexes. The present work is we feel valuable in this respect

2 *Nystagmus due to dysfunction of the lumbar proprioceptors*

We have already reported that when the unilateral neck muscles, especially the deep nuchal muscles of rabbits were paralyzed by procaine or activated by electric stimulation animals often developed *spontaneous nystagmus*. This nystagmus can be induced in rabbits without a labyrinth. But no nystagmus can be observed on unilateral procainization of the superficial nuchal muscles of normal rabbits (Fukui 1971 Ishida, 1972) Igarashi and his co-workers also induced nystagmus of this type in monkeys (Igarashi et al 1969) However there have been no systematic observations on whether nystagmus of this type can be induced from the lumbar erector muscles in human subjects. Yoshii and his co-workers reported that several cases, suffering from tuberculous caries of the thoracic and lumbar spines, developed positional nystagmus associated with positional vertigo But, they did not report that these cases showed spontaneous nystagmus (Yoshii et al 1960) Yamada & Hinoki found that cases with thoracic and lumbar scoliosis sometimes developed spontaneous nystagmus associated with asymmetric EMG s from the lumbar region and that decrease in these EMG s on wearing an active corrective plaster jacket was parallel with reduction in spontaneous nystagmus (Yamada & Hinoki, 1968) These findings suggest that spontaneous nystagmus can be induced by functional imbalance between the right and left lumbar proprioceptors. However there is no definite evidence as to whether nystagmus of this type can be induced in normal subjects on unequal suppression or excitation of the lumbar proprioceptors. Furthermore apart from the two groups of diseases just mentioned it is unknown what kinds of diseases can cause nystagmus of lumbar origin So it is, we feel, valuable to have clarified the fact that spontaneous nystagmus can be induced in normal subjects on unilateral procainization of the lumbar erector muscles. It is also interesting that traumatized patients with unilateral or predominantly unilateral lumbago often developed spontaneous nystagmus, and that this nystagmus decreased significantly or disappeared after unilateral procainization of tender spots in the lumbar erector muscles. Incidentally the nystagmus induced in normal subjects was usually horizontal, and was also usually a mixed type of nystagmus in which the nystagmus varied significantly in the two directions and the eyes jerked to the right and left This of course, differs appreciably from nystagmus of labyrinthine or optokinetic origin

3. *Neural mechanism of development of two phases of the proprioceptive reflex of lumbar origin, with special reference to cerebellar function*

The question then arises as what parts of the brain are closely related with production of two phases of the proprioceptive reflex of lumbar origin. We have already reported that dysfunction of the central nervous system, especially the brain stem and the cerebellum is important in producing vertigo of cervico-lumbo-muscular origin (Ushio, 1971 Hinoki, 1972). Of the two the cerebellum plays the major role in the development of vertigo of lumbar origin. So we wondered if this part of the brain could be especially related with development of two phases of the proprioceptive reflex. In connection with this possibility the following facts seem noteworthy

1 As described above, on unilateral procainization of the lumbar erector muscles of normal subjects, the subjects often developed spontaneous nystagmus as well as bodily ataxia, as indicated by disturbances of the righting reflex and drift reactions of the lower limbs with ataxic features. Cerebellar ataxia, such as dysmetria or dysdiadochokinesis of the hands appeared at the same time and its development was well correlated with the development of disequilibrium of the eyes and body

2. Unilateral procainization of tender spots in the lumbar erector muscles of traumatized patients often produced the opposite effects to those in normal subjects. Namely it caused reduction in both spontaneous nystagmus and disturbances of the righting reflex. Drift reactions of the lower limbs became opposite in direction and ataxic features decreased after procainization. At the same time, cerebellar ataxia decreased in parallel with reduction in impairment of the righting reflex and changes in the drift reactions of the lower limbs. However this decrease in cerebellar ataxia was not very closely correlated with reduction in spontaneous nystagmus.

From these findings we may conclude that there is a close correlation between changes in bodily equilibrium, such as the righting reflex and drift reactions of the lower limbs, and changes in cerebellar function. This means that two phases of the proprioceptive reflex of lumbar origin, particularly those related to bodily equilibrium depend greatly on cerebellar function. This idea is compatible with findings of fiber connections of the central nervous system. That is, the lumbar proprioceptors are closely connected to the cerebellum through centripetal paths, such as the posterior spinocerebellar tract. Of course, the brain stem may also be related with changes in bodily reflexes caused by procainization of the lumbar erector muscles, because the lumbar proprioceptors are also connected to the brain stem through centripetal paths, such as the spinoreticular tract. However the intimate correlation between changes in bodily equilibrium and those in cerebellar function in these cases suggest that the cerebellum is more important than the brain stem in development of two phases of the proprioceptive reflex, particularly those related to bodily equilibrium.

From the neuroanatomical point of view the cerebellum may also affect development of spontaneous nystagmus, because the flocculonodular lobe of the cerebellum is known to be important in producing nystagmus. Recently Kornhuber & Sakata reported that lesions of the intermediate part of the vermis, particularly the fastigal nucleus, can produce nystagmus, because this nucleus is closely connected to the brain stem reticular formation and the vestibular nuclei (Kornhuber 1968 Sakata, 1971). Using cats, Eager reported that the posterior spinocerebellar tract terminates in the homolateral anterior lobe of the cerebellum and connects to the fastigal nucleus (Eager 1963). According to Niimi, Eager's findings seem compatible with those in human beings (Niimi, 1973*a*). Thus, centripetal impulses from the lumbar proprioceptors affect eye reflexes through the neural elements just mentioned. However after procainization the correlation between changes in eye reflexes, particularly spontaneous nystagmus and those in cerebellar function was less obvious than the correlation between changes in bodily

1 Einleitung

Der endemische Kretinismus in Zusammenhang mit Hör- und Sprachstörungen ist seit langem bekannt und hat immer wieder Diskussionen entfacht, inwieweit und ob überhaupt der Schilddrüse eine Bedeutung für die normale Entwicklung des Ohres zukommt. Ist es doch eine Tatsache, dass die Verbreitung der Gehörstörungen weder mit der Häufigkeit des endemischen Kretinismus noch mit der Intensität der Kropfendemie parallel geht (Trotter 1960, Greenwald, 1960, Costa und Ferraris 1963). Erste Beschreibungen derartiger Krankheitsbilder gehen in frühe Zeitepochen zurück. So berichten römische Autoren über den Alpenkropf (Juvenal und Virtuv). Im 16. und 17. Jahrhundert weisen besonders Schweizer Ärzte wie Paracelsus und Felix Plater (1530–1619) auf den Kretinismus hin, wobei Plater als erster auf das Vorkommen von Taubstummheit mit kropfiger und kretiner Degeneration hinwies. In seinem 1656 in Basel erschienenen Buch „praxos medicae opus cum centuria posthuma, emendatum et auct. a Felice Platero" erwähnt er eine Art von Taubheit, die in den Alpengegenden auftritt und durch Taubstummheit in Verbindung mit einem Kropf charakterisiert ist. Ätiologisch nimmt Plater an, dass die Erkrankung durch eine vom Kropf zum Ohr hin fliessende Flüssigkeit hervorgerufen wird. Er schreibt: Sicuti in alpinis regionibus, hac de causa multos difficilem auditum ab ortu, vel mox in aetatis progressu una cum strumis illis ob similem causam familiaribus habere cernimus (nach Politzer 1907).

Eingehende Untersuchungen zu diesem Problemkreis blieben Forschern im vorigen Jahrhundert vorbehalten – allen voran H. Bircher (1883), dessen Ausführungen zur endemischen Taubstummheit grundlegende Aspekte eröffnete. Die Untersuchungen wandten sich jetzt mikromorphologischen Methoden zu, was durch den weiteren Ausbau der Othistologie mit ihrer verfeinerten Technik wesentlich erleichtert wurde. Siebenmann (1906), Oppikofer (1913), Schlittler (1917), Brock (1920) und Nager (1921) stellten keine krankhaften Veränderungen des peripheren Hörorgans fest und hielten als Ursache für die Sprach- und Gehörstörungen eine zentrale Schädigung für wahrscheinlich. Andererseits bestand für die damaligen Autoren kein Zweifel, dass im peripheren Hörorgan beim voll ausgebildeten Krankheitsbild des endemischen Kretinismus typische morphologische Veränderungen nachweisbar sein können. Einmal Veränderungen im Mittelohr wie fehlende Pneumatisation des Warzenfortsatzes, mangelhaft angelegtes Antrum, Verengerung der Paukenhöhle, kleine Fensternischen, Verklumpungen von Gehörknöchelchen, Verdickung der Mittelohrschleimhaut, zum anderen Alterationen des Innenohres, die jedoch nur geringgradig ausgeprägt waren wie „atrophische Zustände der Hörzellen des Cortiorgans und der Ganglienzellen", auch Veränderungen der Stria vascularis (Alexander 1909, 1919), „eigentümliche Bildung des Cortiorgans (hyaline säulenförmige Leiste)" (Siebenmann 1904, Schlittler 1917, Nager 1917, Mayer 1919, Oppikofer 1921, Steurer 1922*a, b*).

Anlass zu vorliegender Studie war die Fülle von Publikationen mit mehr oder weniger wahrscheinlichen morphologischen Befunden am Hörorgan schilddrüsengestörter Patienten sowie der experimentell weitgehend ungeklärte Einfluss des Schilddrüsenhormons auf die Feinstrukturen des Innenohres. Die früheren Untersuchungen beschränkten sich fast ausschliesslich auf Beschreibungen von Krankheitsfällen des endemischen Kretinismus und der im späteren Lebensalter erworbenen Hypothyreose mit konsekutiver Hör-

2 Methodik

2.1 Versuchstiere, operative Massnahmen

Als Versuchstiere wurden 70 Meerschweinchen eines Inzuchtstammes im Gewicht von 250–350 g gewählt. Das Meerschweinchen erweist sich insofern als geeignetes Versuchstier, weil es besonders günstige Voraussetzungen für die anatomische Darstellung des Hörorgans mit Saccus endolymphaticus bietet. In Vollnarkose (intraperitoneal 0,015/100 g Körpergewicht Urethan oder Nembutal 0,004/100 g Körpergewicht) mit zusätzlicher lokaler 1%iger Novocain-Injektion wurde unter dem *Zeiss-Operationsmikroskop eine* vollständige *Thyreoidektomie durchgeführt.* Während der Vorversuche *zur* Erprobung der Operationstechnik der Thyreoidektomie verstarben einige Tiere am Operationstag, was auf eine zu lange Operationsdauer und eine zu starke Dehnung der *Halsweichteile mit* Überstreckung des Nervus vagus und Nervus sympathicus *zurückzuführen ist.* Die *meisten* Tiere vertrugen jedoch den Eingriff ohne wesentliche Komplikationen. Die Tötung der Tiere erfolgte nach 6–9 Wochen p. o. durch Dekapitation *in leichter Äthernarkose. Zur gleichen Zeit* wurden 10 Kontrolltiere getötet. Vor dem operativen Eingriff und unmittelbar vor der Tötung der Tiere wurde das Hörvermögen mittels des Preyer-Reflexes durch Händeklatschen in 1, 3 und 5 m Entfernung geprüft.

2.2 Präparatorische Arbeiten an der Cochlea und am Saccus endolymphaticus

Nach Entfernung der Schädelkalotte und Herauslösen des Gehirns wurde das Felsenbein eliminiert und die Bulla tympani – entsprechend der menschlichen Anatomie der Paukenhöhle – eröffnet. Um eine ausreichende Fixierung der Innenohrstrukturen zu erzielen, wurde der Stapes aus dem ovalen *Fenster* herausgelöst, *gleichzeitig* das *runde Fenster eröffnet.* Nur so wird eine *optimale* Zirkulation der *Fixierungslösung gewährleistet.* Zur Fixierung wurden eine Formalin-Calcium-Lösung nach Baker (1944) sowie das Greepsche Gemisch verwendet. Ausserdem wurden einige Schnecken zum Nachweis der Sulfhydryle mit Trichloressigsäure-Alkohol fixiert. Die rechte Schnecke, die *jeweils für* die *Fermentuntersuchungen* verwendet wurde, blieb für 3–6 Std. bei 4°C in dem Bakerschen Fixativ. Die linke Schnecke, die für die Untersuchungen des Mukopolysaccharidstoffwechsels vorgesehen war, fixierten wir im gleichen Gemisch über etwa 4 Std. Der Saccus endolymphaticus wurde lediglich für 2 Std. fixiert, da es sich hier nur um ein sehr kleines Gewebsstück handelt.

Nach der Fixierung wurde bei einem Teil der Schnecken die knöcherne Begrenzung des häutigen Labyrinthes unter dem Mikroskop *vollständig entfernt und* das Gewebsmaterial in Gelatine eingebettet. Bei dem anderen Teil wurde mit dem Bohrer der Knochen bis auf eine dünne Schicht abgefräst, danach erfolgte für ca. 3–5 Tage eine Entkalkung mit EDTA (Äthylen-Diamin-Tetra-Essigsäure). In besonderem Maße muss bei dieser Art der Entkalkung auf konstante Bedingungen geachtet werden: pH-Wert um 7,0, Temperatur 4°C und 1stündiger Wechsel der Entkalkungsflüssigkeit (Balogh *und* Nomura, *1964*; Nomura und Balogh, 1964*a*, *b*; Ishii und Balogh, *1966*). *Die linke Cochlea, die für die* Untersuchungen zum Mukopolysaccharidstoffwechsel vorgesehen war, wurde *nach der 24stündigen* Fixierung im Greep-Gemisch (Ameisensäure-Natrium-*Zitrat*) *entkalkt* (Greep et al., *1948*) und anschliessend in Paraffin eingebettet. *Die Paraffineinbettung* ist für den Nach-

störung Experimentelle Untersuchungen der neueren Zeit stammen von Poulsen (1959) Ritter und Lawrence (1960) de Vos (1963) Ritter (1967)

Die eigenen Untersuchungen gehen vom thyreoidektomierten Meerschweinchen aus, quasi als Modell für die im späteren Lebensalter erworbenen Hypothyreosen und sollen die Frage beantworten inwieweit mit Hilfe histochemischer Methoden etwaige durch den Tyroxinmangel hervorgerufene Veränderungen im Innenohr des Meerschweinchens nachweisbar werden und ob die Alterationen nähere Aufschlüsse über den Einfluss der Schilddrüsenhormone auf die Innenohrstrukturen ermöglichen Von vornherein muss man sich darüber Rechenschaft geben dass nur ein Abschnitt im komplexen Ablauf des Krankheitsbildes sichtbar wird und besonders elektrophysiologische Untersuchungen eine wertvolle Erweiterung der Experimente darstellen würden Dennoch lassen die in jüngster Zeit verfeinerten Methoden histochemischer Innenohrexploration die Hoffnung zu auch mit Hilfe der Morphologie Aussagen über eine mögliche Funktionsbeeinträchtigung machen zu können

2 Methodik

2.1 Versuchstiere, operative Massnahmen

Als Versuchstiere wurden 70 Meerschweinchen eines Inzuchtstammes im Gewicht von 250-350 g gewählt. Das Meerschweinchen erweist sich insofern als geeignetes Versuchstier, weil es besonders günstige Voraussetzungen für die anatomische Darstellung des Hörorgans mit Saccus endolymphaticus bietet. In Vollnarkose (intraperitoneal 0,015/100 g Körpergewicht Urethan oder Nembutal 0,004/100 g Körpergewicht) mit zusätzlicher lokaler 1%iger Novocain-Injektion wurde unter dem Zeiss-Operationsmikroskop eine vollständige Thyreoidektomie durchgeführt. Während der Vorversuche zur Erprobung der Operationstechnik der Thyreoidektomie verstarben einige Tiere am Operationstag, was auf eine zu lange Operationsdauer und eine zu starke Dehnung der Halsweichteile mit Überstreckung des Nervus vagus und Nervus sympathicus zurückführen ist. Die meisten Tiere vertrugen jedoch den Eingriff ohne wesentliche Komplikationen. Die Tötung der Tiere erfolgte nach 6-9 Wochen p. o. durch Dekapitation in leichter Äthernarkose. Zur gleichen Zeit wurden 10 Kontrolltiere getötet. Vor dem operativen Eingriff und unmittelbar vor der Tötung der Tiere wurde das Hörvermögen mittels des Preyer-Reflexes durch Händeklatschen in 1, 3 und 5 m Entfernung geprüft.

2.2. Präparatorische Arbeiten an der Cochlea und am Saccus endolymphaticus

Nach Entfernung der Schädelkalotte und Herauslösen des Gehirns wurde das Felsenbein eliminiert und die Bulla tympani – entspricht in der menschlichen Anatomie der Paukenhöhle – eröffnet. Um eine ausreichende Fixierung der Innenohrstrukturen zu erzielen, wurde der Stapes aus dem ovalen Fenster herausgelöst, gleichzeitig das runde Fenster eröffnet. Nur so wird eine optimale Zirkulation der Fixierungslösung gewährleistet. Zur Fixierung wurden eine Formalin-Calcium-Lösung nach Baker (1944) sowie das Greepsche Gemisch verwendet. Ausserdem wurden einige Schnecken zum Nachweis der Sulfhydryle mit Trichloressigsäure-Alkohol fixiert. Die rechte Schnecke, die jeweils für die Fermentuntersuchungen verwendet wurde, blieb für 3-6 Std. bei 4°C in dem Bakerschen Fixativ. Die linke Schnecke, die für die Untersuchungen des Mukopolysaccharidstoffwechsels vorgesehen war, fixierten wir im gleichen Gemisch über etwa 4 Std. Der Saccus endolymphaticus wurde lediglich für 2 Std. fixiert, da es sich hier nur um ein sehr kleines Gewebsstück handelt.

Nach der Fixierung wurde bei einem Teil der Schnecken die knöcherne Begrenzung des häutigen Labyrinthes unter dem Mikroskop vollständig entfernt und das Gewebsmaterial in Gelatine eingebettet. Bei dem anderen Teil wurde mit dem Bohrer der Knochen bis auf eine dünne Schicht abgefräst, danach erfolgte für ca. 3-5 Tage eine Entkalkung mit EDTA (Äthylen-Diamin-Tetra-Essigsäure). In besonderem Maße muss bei dieser Art der Entkalkung auf konstante Bedingungen geachtet werden: pH-Wert um 7,0, Temperatur 4°C und 1-stündiger Wechsel der Entkalkungsflüssigkeit (Balogh und Nomura, 1964; Nomura und Balogh, 1964*a*, *b*; Ishii und Balogh, 1966). Die linke Cochlea, die für die Untersuchungen zum Mukopolysaccharidstoffwechsel vorgesehen war, wurde nach der 24stündigen Fixierung im Greep-Gemisch (Ameisensäure-Natrium-Zitrat) entkalkt (Greep et al. 1948) und anschliessend in Paraffin eingebettet. Die Paraffineinbettung ist für den Nach-

weis von Mukopolysacchariden möglich da die zwischenzeitliche Behandlung der Schnitte mit Alkohol und Benzol – im Gegensatz zum Fermentnachweis – keinen Aktivitätsverlust nach sich zieht In ähnlicher Weise wurde mit dem Saccus endolymphaticus verfahren der rechte Saccus diente den Fermentuntersuchungen der linke wurde für den Mukopolysaccharidstoffwechsel vorgesehen wobei natürlich eine Entkalkung nicht erforderlich war

2.3 Spezielle fermenthistochemische Nachweisverfahren

2 3 1 *Unspezifische Esterasen*

Die unspezifische Esterase wurde nach Burstone (1957) mit Naphthol AS D-Azetat und Kupplung an Echtblausalz RR nachgewiesen Durch den Einfluss der Esterasen wird das Azetat abgespalten und der Naphtholrest frei gesetzt Dieser Naphtholrest hat ein hohes Eiweissbindungsvermögen und heftet sich somit an Stellen der fermentativen Gewebsaktivität am Protein an Um den an Eiweiss gebundenen Naphtholrest sichtbar zu machen wird ein Diazoniumsalz angekuppelt (z. B Echtblausalz RR Echtgranatsalz GBC u a.) Dadurch wird eine Fermentaktivität in Form von Farbkörnchen sichtbar gemacht

Zur Kontrolle der Spezifität wird an einzelnen Schnitten entweder das Substrat oder das Diazoniumsalz weggelassen Die unspezifischen Esterasen und Cholinesterasen werden nach Barrnett und Seligman (1951) durch Gaben von 10^{-3} M Natriumtaurocholat gehemmt Cholin und B Esterasen werden durch 10^{-8} M Diiso-Propylfluorophosphat die A Esterasen durch 10^{-4} M Natrium-Chloro-Mercuri-Benzoat gehemmt (Bergmann und Rimon 1958)

2 3 2 *β-Glukuronidase*

Die Darstellung der Glukuronidase erfolgt durch Inkubation der etwa 12 μ dicken Gelatineschnitte in der Substratlösung nach Seligman et al (1954) mit 6-Bromo-2 Naphthyl β-D-Glukuronid bei pH 4 9 und 37°C für 4–6 Std Danach wurde eine Postkupplung mit Echtblausalz RR und Echtgranatsalz GBC bei pH 7,5 vorgenommen Zur Kontrolle der Spezifität wurden Reaktionen mit alleiniger Echtblausalz-bzw Echtgranatsalzfärbung (ohne Substratinkubation) und alleiniger Substratinkubation (ohne Kupplung) durchgeführt Um eine Enzymdiffusion zu verhindern wurde der Substratlösung jeweils 1 M NaCl zugefügt (Schätzle und v Westernhagen 1966*b*)

2.3.3 *N Azetyl β-Glukosaminidase*

Die Glukosaminidase wurde in einem von Schätzle und v Westernhagen (1966*a*) leicht modifizierten Verfahren nach Pugh und Walker (1958 1961) durchgeführt Zum Nachweis wurde statt des Originalsubstrates Alpha Naphthyl Azetyl-β-Glukosamin das stabilere Naphthol AS LC N Azetyl β D Glukosamin verwendet Danach erfolgte Kupplung an ein Diazoniumsalz (Echtgranatsalz GBC) als Simultankupplung unter gleichen pH Bedingungen Einzelne Schnitte wurden auf ihre Fermentspezifität untersucht indem das Substrat fortgelassen oder aber mit Substrat eine über Wochen dauernde Formolfixierung durchgeführt wurde welche das Ferment inaktiviert

2.3 4 *β-Galaktosidase*

Hierbei wurde die Methode von Rutenburg et al (1958) angewandt 12 μ dicke Gefrierschnitte wurden für 3–12 Std in einer Lösung von 6-Bromo-2 Naphthyl β-D-Galaktosid bei pH 4 95 und 37°C Temperatur inkubiert Die anschliessende Kupplung erfolgte mit Echtgranatsalz GBC Danach wurde bei pH 7 4 und Zimmertemperatur 10–15 Min nachgekuppelt.

Daneben wurden auch Schnitte mit Naphthol AS LC β-D-Galaktosid als Substrat (1? Std bei pH 4,95 und 37°C Temperatur) in Verbindung mit Echtgranatsalz GBC Postkupplung (10 Min pH 7 4 Raumtemperatur) behandelt

Die Kontrollreaktionen wurden an inkubier

ten Schnitten ohne Diazokupplung sowie an nicht substratinkubierten Schnitten durchgeführt.

3.5 Aryl Sulfatase

Gefrierschnitte von 12 β Dicke wurden für 4–6 Std bei 37°C und pH 6.1 in einer Lösung von Kalium-6-Benzoyl-2-Naphthylsulfat nach Rutenburg und Seligman (1956) inkubiert. Wie in der Originalmethode beschrieben, wurde Kochsalz zugesetzt. Nach kurzer Wässerung erfolgte die Postkupplung mit Echtgranatsalz GBC oder Echtrotsalz TR bei pH 7.6 (ca. 10 Min.) bei Raumtemperatur.

Kontrollreaktionen wurden unter Weglassung des Substrates sowie mit alleiniger Inkubation ohne nachfolgende Kupplung ausgeführt.

2.4 Nachweis der Sulfhydryle und Gesamtsulfhydryle

Die für die Untersuchung von Sulfhydrylen vorgesehenen Schnecken wurden mit Trichloressigsäure-Alkohol fixiert, anschliessend erfolgte eine kurzdauernde Entkalkung mit EDTA. Die 10 µ dicken Paraffinschnitte wurden wie folgt bearbeitet.

4.1 Sulfhydrylnachweis nach Barrnett und Seligman (1952, 1954)

mit dem DDD-Reagens bei pH 8.5 mit Veronal-Azetat Puffer und Kupplung an Echtgranatsalz GBC bei pH 7.4 mit Phosphatpuffer. Durch die Verwendung von Echtgranatsalz entsteht eine Rotfärbung. Die Kontrollreaktion erfolgte durch Blockierung der freien SH-Gruppen mittels eines Zusatzes von Monojodessigsäure (0.1 M); die „freien" SH-Gruppen wurden mittels Sublimat blockiert.

4 Gleichzeitiger Nachweis von Sulfhydrylen und Disulfiden (Gesamtsulfhydryle)

Es erfolgte eine Überführung der SS-Gruppen in SH-Gruppen durch Thioglykolsäure (0.5 M bei 37°C und pH 8.0), danach Nachweis der Gesamtsulfhydryle mit der DDD-Methode.

2.5 Histochemischer Nachweis von Gluko-Mukoproteiden, sauren Mukopolysacchariden

2.5.1 PAS-Reaktion nach McManus (1946) Hotchkiss (1948)

Nach Formalinfixierung und Entkalkung erfolgt die Paraffineinbettung.

2.5.2 PAS-Alcianblau nach Runge, Ebner und Lindenschmidt (1956)

Als Kontrollreaktion wurde eine Methylierung des Schnittes durchgeführt, was sich infolge Blockierung saurer Substanzen in einer verringerten Anfärbbarkeit dokumentiert (Fraenkel-Conrat und Olcott, 1945; Fisher und Lillie 1954). Ausserdem wendeten wir die Sulfatierung nach Kramer und Windrum (1954) an. Mit dieser Methode lassen sich zusätzliche Sulfatgruppen auf ein entsprechendes Substrat übertragen. Durch die Zunahme der Sulfatgruppen resultiert eine stärkere Metachromasie-Reaktion.

Die Reaktionen 1 und 2 wurden ergänzt durch die Anwendung von Amylase, Ribonuklease und Hyaluronidase, um die den angeführten Fermenten entsprechenden Substrate aus dem Schnitt zu entfernen.

2.5.3 Eisenbindungsreaktion nach Hale (1946)

Eisenbindungsreaktion in der Modifikation *nach Graumann und Clauss (1958)* oder *Hale* PAS-Reaktion nach Ritter und Oleson (1950).

5.4 Metachromasie-Reaktionen

5.4.1 Azur-A 0.2%ig bei verschiedenen pH-Werten (1.5, 3.5, 4.5) *mit* Walpole Puffer an Paraffinschnitten (Walpole 1914). Es erfolgten die gleichen Kontrollreaktionen wie unter PAS-Alcianblaufärbung oben angeführt. Vor der Reaktion wurden die Schnitte mit Ribonuklease behandelt, um Nukleinsäure herauszulösen. Weitere Kontrollreaktionen erfolgten mit Hyaluronidase, um die hyaluronidasesensiblen MPS zu entfernen.

weis von Mukopolysacchariden möglich da die zwischenzeitliche Behandlung der Schnitte mit Alkohol und Benzol – im Gegensatz zum Fermentnachweis – keinen Aktivitätsverlust nach sich zieht In ähnlicher Weise wurde mit dem Saccus endolymphaticus verfahren der rechte Saccus diente den Fermentuntersuchungen der linke wurde für den Mukopolysaccharidstoffwechsel vorgesehen wobei natürlich eine Entkalkung nicht erforderlich war

2.3 Spezielle fermenthistochemische Nachweisverfahren

2 3 1 *Unspezifische Esterasen*

Die unspezifische Esterase wurde nach Burstone (1957) mit Naphthol AS-D-Azetat und Kupplung an Echtblausalz RR nachgewiesen Durch den Einfluss der Esterasen wird das Azetat abgespalten und der Naphtholrest freigesetzt Dieser Naphtholrest hat ein hohes Eiweissbindungsvermögen und heftet sich somit an Stellen der fermentativen Gewebsaktivität am Protein an Um den an Eiweiss gebundenen Naphtholrest sichtbar zu machen wird ein Diazoniumsalz angekuppelt (z B Echtblausalz RR Echtgranatsalz GBC u a) Dadurch wird eine Fermentaktivität in Form von Farbkörnchen sichtbar gemacht

Zur Kontrolle der Spezifität wird an einzelnen Schnitten entweder das Substrat oder das Diazoniumsalz weggelassen Die unspezifischen Esterasen und Cholinesterasen werden nach Barrnett und Seligman (1951) durch Gaben von 10^{-3} M Natriumtaurocholat gehemmt Cholin und B Esterasen werden durch 10^{-5} M Diiso-Propylfluorophosphat die A Esterasen durch 10^{-4} M Natrium-Chloro-Mercuri Benzoat gehemmt (Bergmann und Rimon 1958)

2 3 2 *β-Glukuronidase*

Die Darstellung der Glukuronidase erfolgt durch Inkubation der etwa 12 μ dicken Gelatineschnitte in der Substratlösung nach Seligman et al (1954) mit 6-Bromo-2 Naphthyl β-D-Glukuronid bei pH 4 9 und 37°C für 4–6 Std Danach wurde eine Postkupplung mit Echtblausalz RR und Echtgranatsalz GBC bei pH 7,5 vorgenommen Zur Kontrolle der Spezifität wurden Reaktionen mit alleiniger Echtblausalz-bzw Echtgranatsalzfärbung (ohne Substratinkubation) und alleiniger Substratinkubation (ohne Kupplung) durchgeführt. Um eine Enzymdiffusion zu verhindern wurde der Substratlösung jeweils 1 M NaCl zugefügt (Schätzle und v Westernhagen 1966*b*)

2 3.3 *N A etyl β-Glukosaminidase*

Die Glukosaminidase wurde in einem von Schätzle und v Westernhagen (1966*a*) leicht modifizierten Verfahren nach Pugh und Walker (1958 1961) durchgeführt Zum Nachweis wurde statt des Originalsubstrates Alpha Naphthyl-Azetyl β-Glukosamin das stabilere Naphthol AS LC N Azetyl β D Glukosamin verwendet Danach erfolgte Kupplung an ein Diazoniumsalz (Echtgranatsalz GBC) als Simultankupplung unter gleichen pH Bedingungen Einzelne Schnitte wurden auf ihre Fermentspezifität untersucht indem das Substrat fortgelassen oder aber mit Substrat eine über Wochen dauernde Formolfixierung durchgeführt wurde welche das Ferment inaktiviert.

2 3 4 *β-Galaktosidase*

Hierbei wurde die Methode von Rutenburg et al (1958) angewandt 12 μ dicke Gefrierschnitte wurden für 3–12 Std in einer Lösung von 6-Bromo-2 Naphthyl β-D-Galaktosid bei pH 4 95 und 37°C Temperatur inkubiert Die anschliessende Kupplung erfolgte mit Echtgranatsalz GBC Danach wurde bei pH 7 4 und Zimmertemperatur 10–15 Min nachgekuppelt

Daneben wurden auch Schnitte mit Naphthol AS-LC β-D-Galaktosid als Substrat (1? Std bei pH 4 95 und 37°C Temperatur) in Verbindung mit Echtgranatsalz GBC Postkupplung (10 Min pH 7 4 Raumtemperatur) behandelt

Die Kontrollreaktionen wurden an inkubier

, Schnitten ohne Diazokupplung sowie an ht substratinkubierten Schnitten durchge rt.

.3 Aryl Sulfatase

efrierschnitte von 12 μ Dicke wurden für 6 Std bei 37°C und pH 6 1 in einer Lösung n Kalium-6-Benzoyl-2 Naphthylsulfat nach ttenburg und Seligman (1956) inkubiert. Wie der Originalmethode beschrieben, wurde ochsalz zugesetzt. Nach kurzer Wässerung folgte die Postkupplung mit Echtgranatsalz BC oder Echtrotsalz TR bei pH 7 6 (ca. 10 in.) bei Raumtemperatur

Kontrollreaktionen wurden unter Weglas ung des Substrates sowie mit alleiniger In- ubation ohne nachfolgende Kupplung ausge ührt

.4 Nachweis der Sulfhydryle und Gesamtsulfhydryle

Die für die Untersuchung von Sulfhydrylen vorgesehenen Schnecken wurden mit Trichlor essigsäure Alkohol fixiert, anschliessend er folgte eine kurzdauernde Entkalkung mit EDTA Die 10 μ dicken Paraffinschnitte wur den wie folgt bearbeitet

.4 1 Sulfhydrylnachweis nach Barnett und Seligman (195 1954)

mit dem DDD-Reagens bei pH 8,5 mit Vero- nal Azetat Puffer und Kupplung an Echt granatsalz GBC bei pH 7 4 mit Phosphatpuffer Durch die Verwendung von Echtgranatsalz entsteht eine Rotfärbung Die Kontrollreak tion erfolgte durch Blockierung der freien SH Gruppen mittels eines Zusatzes von Monojod- essigsäure (0 1 M) die „tragen" SH-Grup- pen wurden mittels Sublimat blockiert

.4 2 Gleichzeitiger Nach eis on Sulfhy drylen nd Disulfiden (Gesamtsulfhydryle)

Es erfolgte eine Überführung der SS-Gruppen in SH-Gruppen durch Thioglykolsäure (0,5 M bei 37°C und pH 8 0), danach Nachweis der Gesamtsulfhydryle mit der DDD-Methode.

2.5 Histochemischer Nachweis von Gluko- Mukoproteiden, sauren Mukopoly- sacchariden

2.5 1 PAS-Reaktion nach McManus (1946) Hotchkiss (1948)

Nach Formalinfixierung und Entkalkung er folgt die Paraffineinbettung.

2.5 2. PAS Alcianblau nach Runge Ebner und Lindenschmidt (1956)

Als Kontrollreaktion wurde eine Methylierung des Schnittes durchgeführt, was sich infolge Blockierung saurer Substanzen in einer ver ringerten Anfärbbarkeit dokumentiert (Fraen- kel-Conrat und Olcott, 1945 Fisher und Lillie 1954) Ausserdem wendeten wir die Sulfatie rung nach Kramer und Windrum (1954) an. Mit dieser Methode lassen sich zusätzliche Sul- fatgruppen auf ein entsprechendes Substrat übertragen Durch die Zunahme der Sulfat gruppen resultiert eine stärkere Metachroma sie Reaktion

Die Reaktionen 1 und 2 wurden ergänzt durch die Anwendung von Amylase Ribonu- klease und Hyaluronidase um die den ange führten Fermenten entsprechenden Substrate aus dem Schnitt zu entfernen.

.5 3 Eisenbindungsreaktion nach Hale (1946)

Eisenbindungsreaktion in der Modifikation nach Graumann und Clauss (1958) oder Hale PAS-Reaktion nach Ritter und Oleson (1950)

2.5 4 Metachromasie Reaktionen

.5 4 1 Azur A 0,2 %ig bei erschiedenen pH Werten (1,5 3,5 4,5) mit Walpole Puffer an Paraffinschnitten (Walpole 1914) Es erfolg ten die gleichen Kontrollreaktionen wie unter „PAS-Alcianblaufärbung" oben angeführt Vor der Reaktion wurden die Schnitte mit Ri- bonuklease behandelt, um Nukleinsäure her auszulösen. Weitere Kontrollreaktionen er folgten mit Hyaluronidase um die hyaluroni- dasesensiblen MPS zu entfernen

3 Experimentelle Untersuchungsergebnisse – Kontrolltiere (Meerschweinchen)

3.1 Normale fermenthistochemische Befunde der Cochlea

3.1.1 *Unspezifische Esterase*

Die Esterasereaktion fällt intensiv positiv an den Deiters- und Hensenzellen aus, also in den dem Stützzellensystem zuzuordnenden Zellen. Die Sinneszellen reagieren deutlich geringer; von ihnen haben die inneren Haarzellen im Vergleich zu den äusseren eine relativ kräftigere Blaufärbung. Die Basilarmembran ist negativ, positiv die sog. tympanale Belegschicht sowie die Stria vascularis. Sulcus spiralis externus und internus sind in ihrem epithelialen Bereich kräftig positiv.

3.1.2 *β-Glukuronidase*

Eine mässige bis starke Reaktion zeichnet sich im Bereich des N. acusticus ab, während das Cortiorgan wesentlich schwächer positiv war. In allen anderen Abschnitten des Ductus cochlearis sieht man bei der Kupplung an Echtgranatsalz GBC geringfügige bis schwach granatrote Granula. Besonders in der apikalen und perinukleären Zone der inneren und äusseren Haarzellen. Die Basilarmembran ist negativ, es findet sich eine mässige Rotfärbung der tympanalen Belegschicht. Auffällig ist eine stärkere Reaktion in der Reissnerschen Membran, die sich in etwas geringfügigerer Intensität auch in der Stria vascularis wiederholt.

3.1.3 *N-Acetyl-β-Glukosaminidase*

Der auffallendste Befund ist die intensive Enzymreaktion der äusseren Haarzellen und hier besonders in der apikalen Zone. Die inneren Haarzellen dagegen zeigen eine schwächere Fermentaktivität. Die Zellen des Sulcus spiralis besitzen eine schwächere Fermentaktivität. Die Zellen des Sulcus spiralis externus zeigen insgesamt nur eine schwache Reaktion. Kräftig dagegen reagiert die Stria vascularis.

3.1.4 *β-D-Galaktosidase*

Die Fasern des N. acusticus sowie die vom Cortiorgan zum Ganglion cochleae ziehenden Fasern weisen eine sehr deutliche Fermentaktivität auf. Ebenso werden reichlich Fermentgranula im Ganglion spirale nachweisbar, während das Cortiorgan vergleichsweise schwach oder fast gar nicht reagiert. Im Plexus cochlearis in der Nähe des N. acusticus zeichnet sich eine stärkere Fermentaktivität ab. Zahlreiche Fermentgranula finden sich zudem in der Stria vascularis zwischen den Pigmentanhäufungen.

3.1.5 *Aryl-Sulfatase*

Es zeigt sich eine intensive Reaktion in den Fasern des N. acusticus sowie in den präganglionären Fasern. Auch die Haarzellen reagieren deutlich positiv, wobei die Farbkörnchen überwiegend perinukleär zu finden sind. Die Stria vascularis verhält sich in ihrer Fermentaktivität kräftig positiv (Tab. 1).

3.2. Normale fermenthistochemische Befunde des Saccus endolymphaticus

Die unspezifischen Esterasen finden sich in mittelstarker Reaktion im Epithel der Pars intermedia des S. e., die Pars distalis reagiert wesentlich schwächer. Von den sog. freien Zellen im Saccuslumen weisen einige Zellen eine erhebliche Fermentaktivität auf, während sich andere praktisch negativ ausweisen.

Die Glukosaminidase-Reaktion verhält sich in der Lokalisation des Fermentes sehr ähnlich dem Esterase-Nachweis, wenn auch die

Tabelle I *Fermenthistochemische Aktivitäten an der Cochlea des Kontrolltiers (Meerschweinchen)*

	Esterase	Glukuronidase	Glukosaminidase	Sulfatase	Galaktosidase
Stria vasc.	+	++	+	++	++
Sulc. spir. ext.	+	+0	+0	+0	+0
Lig. spirale	0	+0	0	+0	+0
Ggl. spirale	0	+	++	+0	++
Äussere HZ	+0	+0	++	+	+0
Innere HZ	+	+	+0	+	+0
Deiters Zellen	++	0	+0	+0	+0
Hensen Zellen	++	+0	+0	0	+0
Pfeiler Zellen	+0	0	0	0	0
Memb. tect.	0	0	0	0	0
Reissner M.	+0	+	+0	0	+0
Basil. M.	0	0	0	0	0
Tymp. Belegsch.	+	0	0	0	+0
Limb. spirale		+0	0	+0	+
N. acusticus	0	+	0	++	++
Prominentia spiralis F.	0	+	0	++	++
Plex. cochlearis	+0	+0	+	+0	+0

Enzymaktivität vergleichsweise stärker ausfällt. Es besteht eine starke Ansammlung von Fermentgranula in der Pars intermedia (Epithel). Ausserdem weisen zahlreiche intrasacculäre Zellen einen hohen Fermentgehalt auf.

Der Nachweis der Glukuronidase und Galaktosidase stimmt weitgehend mit den Ergebnissen von der Esterase und der Glukosaminidase überein, wenn auch insgesamt die Fermentreaktionen etwas schwächer ausfallen.

Die Sulfatase lässt besonders in der Pars intermedia (Epithel) eine sehr starke Fermentaktivität erkennen, die sich auch in den sog. freien Zellen abzeichnet (Tab. II).

3.3 Normale Verteilung von Sulfhydrylen (SH) und Gesamtsulfhydrylen (SS+SH) in der Cochlea

Die Stria vascularis reagiert intensiv positiv (SH-Reaktion), ebenfalls die Pfeilerzellen. Positiv verhalten sich auch die Zellen des Ganglion spirale und die Nervenfasern des N. acusticus. Äussere und innere Haarzellen weisen einen deutlichen, wenn auch nicht hohen SH-Gehalt auf. Mit der Methode nach Barrnett und Seligman lassen sich auch noch positive Bereiche im Limbus spiralis, Lig. spirale und Reissner Membran erfassen. Erwartungsgemäss fallen beim Gesamtsulfhydryl-

Tabelle II *Fermenthistochemische Aktivitäten am Saccus endolymphaticus des Kontrolltiers (Meerschweinchen)*

	Esterase	Glukuronidase	Glukosaminidase	Sulfatase	Galaktosidase
Epithelien Pars intermedia			+		+
Epithelien Pars distalis	+0	+0	+0		0
Bindegewebe	0	0	0	+0	+0
Zellen im Bdg.	0	0		+0	+0
Sog. freie Zellen	+0–	0–+	0–+	–++	+0–+

nachweis (SS- +SH-Gruppen) die Reaktionen noch stärker aus – in der Stria vascularis jedoch relativ geringer als im Lig. spirale oder in den Pfeilerzellen Die SH-Gruppen zeigen an Orten vermehrter Stoffwechseltätigkeit ein Überwiegen z B in der Stria vascularis während die SS-Gruppen (Disulfide) mehr an den Orten vorkommen denen eine Stützfunktion zugeordnet wird (Pfeilerzellen Basilarmembran) (Müsebeck und Schätzle 1963)

3 4 Normale histochemische Befunde von Gluko-Mukoproteiden sauren Mukopolysacchariden in der Cochlea

3 4 1 *PAS Alcianblau-Reaktion (nach Runge Ebner und Lindenschmidt (1956)*

Es findet sich bei der PAS-Alcianblaufärbung eine intensive Reaktion im Bereiche der Basilarmembran sowie den Fasern des Verankerungssystems im Lig. spirale und Limbus spiralis Das Cortiorgan und die tympanale Belegschicht sind praktisch frei Auffallend ist eine stärker blau gefärbte Zone im Bereiche des Ansatzes der Basilarmembran im Lig spirale In der Stria vascularis ist kaum eine Farbreaktion zu erkennen Eine sehr starke Anfärbung zeigt die Tectorialmembran

Durch eine zusätzliche Methylierung werden die sauren Gruppen blockiert was sich im Ausbleiben der Anfärbbarkeit mit Alcianblau zeigt Überträgt man zusätzliche Sulfatgruppen so resultiert daraus keine stärkere Anfärbbarkeit mit Alcianblau Nach Hyaluronidasebehandlung der Schnitte nimmt der Farbton im Bereich der Membrana basilaris und der Membrana tectoria leicht ab

3 4 2 *Eisenbindungsreaktion (nach Hale 1946 modifiziert nach Graumann und Clauss 1958) oder PAS Hale Reaktion (nach Ritter und Oleson 1950)*

Im grossen und ganzen werden ähnliche Farbreaktionen wie bei der PAS-Alcianblaufärbung beobachtet Intensiv reagieren Membrana tectoria und Basilarmembran stark blau gefärbt ist auch die Stria vascularis Die Membrana tectoria weist eine dunkelblaue Farbe auf Auch das bindegewebige zellarme Dreieck am Ansatzpunkt der Basilarmembran am Lig. spirale wird stark angefärbt

Die Kontrollreaktionen ähneln weitgehend den Ergebnissen bei der PAS Alcianblaufärbung unter Anwendung von Methylierung und Sulfatierung.

3 4 3 *Metachromasie Reaktionen*

3 4 3 1 *Azur A* Bei pH 4,5 ergeben sich kräftige metachromatische Reaktionen im Bereiche der Basilarmembran des Knochen Bindegewebes am Modiolus sowie des perivasculären Bindegewebes Eine geringere Metachromasie zeigt sich im Lig. spirale und im bindegewebigen Dreieck an der Ansatzstelle der Basilarmembran am Lig. spirale. Die Stria vascularis verhält sich negativ Eine überaus intensive Metachromotropie weist die Membrana tectoria aus.

Bei pH 3 finden sich Metachromasie Reaktionen in der Basilarmembran und deren Verankerungssystem sehr kräftige Reaktion der Tectorialmembran Stria vascularis und Cortiorgan verhalten sich orthochromatisch

Bei pH 1,5 zeigt sich lediglich eine orthochromatische Reaktion im Bereich der Cochlea

3 4 3 2 *Toluidinblau mit abgestuften $CaCl_2$-Konzentrationen* Bei 0 04 M Lösung des basischen Farbstoffes färben sich nur Stria vascularis und Cortiorgan orthochromatisch an Darüberhinaus lässt sich eine diffuse Rotfärbung an vielen Cochleastrukturen feststellen die zum grössten Teil unspezifisch sein dürfte Ganz ähnliche Verhältnisse finden sich bei 0 1 M Lösungskonzentrationen Erst bei 0 2 M Lösung tritt eine kräftige Metachromasie in der Basilarmembran der Membrana tectoria geringeren Grades auch im Lig spirale und Limbus spiralis auf Die Ergebnisse sind weitgehend vergleichbar mit den Reaktionen von Azur A bei pH 3,5 Bei der 0 4

3.5 Gluko-Mukoproteide, saure Mukopolysaccharide im Saccus endolymphaticus

Bei der PAS-Alcianblaufärbung reagiert das Bindegewebe der Pars intermedia stärker positiv; die Epithelien der Pars intermedia und der Pars distalis sind nur schwach angefärbt oder verhalten sich negativ. Der Inhalt der Saccuslichtung, der sich mit Hämatoxilin-Eosin schwach rosa anfärbt, lässt bei der PAS-Alcianblaufärbung kaum eine Reaktion erkennen. Die sog. freien Zellen im Saccuslumen sind zumeist nicht angefärbt. Bei den Metachromasiemethoden, die an einzelnen Sacci endolymphatici angestellt wurden, fand sich bei Azur A pH 4,5 eine Metachromasie im Bindegewebe der Pars intermedia und distalis. Entsprechend fielen die Ergebnisse der Toluidinblau-Färbung aus. Wegen des nur sehr geringen Gewebsmaterials, welches man bei Entnahme des endolymphatischen Sackes gewinnt, konnten jeweils nicht alle Reaktionen an einem Gewebsstück durchgeführt werden.

4 Experimentelle Untersuchungsergebnisse – thyreoidektomierte Tiere (Meerschweinchen)

4.1 Allgemeines Verhalten der Tiere

8–14 Tage nach der durchgeführten Thyreoidektomie zeigten fast alle Versuchstiere eine deutliche Abnahme der motorischen Aktivität, die Fresslust liess nach, einige Tiere sassen teilnahmslos im Käfig, andere reagierten auffällig aggressiv auf taktile Reize. 9 Tiere liessen nach 6–7 Wochen eine erhebliche Schwerhörigkeit erkennen, was mit Hilfe des Auslösens des Preyer-Reflexes ermittelt werden konnte. Etwa die Hälfte der anderen Tiere zeigten ein herabgesetztes Hörvermögen verschiedener gradueller Abstufung (Auslösen des Preyer-Reflexes in 1–3 m).

4.2 Makroskopische Veränderungen im Bereich der Bulla tympani nach Thyreoidektomie

Von den 9 stark schwerhörigen Tieren war bei 3 Meerschweinchen in der eröffneten Bulla tympani eine verdickte, glasig aussehende Schleimhaut zu erkennen, was als mögliche myxomatöse Veränderung der Mittelohr sehr schwer isolierbar werden. Die myxomatöse Schleimhaut umgibt auch weitgehend das ovale Fenster mit der Stapesnische. Bei 6 der 9 Tiere war es zu einer eitrigen Mittelohrentzündung gekommen, ein Befund, der beim Meerschweinchen schon unter normalen Bedingungen gar nicht so selten ist, im vorliegenden Fall jedoch durch den Hormonmangel begünstigt sein könnte.

4.3 Fermenthistochemische Befunde der Cochlea

4.3.1 *Unspezifische Esterase*

Vergleicht man Abb. 1 (Kontrolltier) mit Abb. 2 (Versuchstier), so lässt sich unschwer die verminderte Fermentaktivität beim Hypothyreosetier feststellen. Das Kontrolltier zeigt eine Reaktion des Fermentes im Bereiche der inneren und äusseren Haarzellen, eine stärkere in den Deiters- und Hensenzellen. Auch in der tympanalen Belegschicht finden sich zahlreiche Farbkörnchen. Die Fermentgranula sind beim Normaltier besonders am apikalen Zellpol der inneren und äusseren Haarzellen lokalisiert.

6 Wochen nach der erfolgten Thyreoidektomie nimmt die Esterase bei fast allen Tieren deutlich ab. Diese Tatsache wird besonders auffällig im Bereich der Sinnes- und Stützzellen (Deiterszellen, Hensenzellen sowie Pfeilerzellen). Auch die recht kräftige Reaktion des Fermentes in der Stria vascularis fällt bei den Versuchstieren ab. Die tympanale Belegschicht an der Lamina basilaris ist praktisch frei von Fermentgranula. In der Reissner-Membran ist gleichfalls eine verminderte Fermentaktivität nachweisbar. Die durchgeführten Spezifitätskontrollen liessen den Schluss zu, dass es sich bei den Farbreaktionen um den Ausdruck der Esteraseaktivität handelt.

4.3.2 *β-Glukuronidase*

Beim Kontrolltier fällt die Glukuronidase-Reaktion besonders kräftig in der Stria vascularis, im N. acusticus und dessen präganglionären Fasern aus. Auch die Reissner-Membran weist eine stärkere Fermentaktivität auf, während die Sinneszellen relativ schwach reagieren. Auf der Übersichtsaufnahme sieht man besonders eindrucksvoll die dunkel gefärbte Stria vascularis sowie die zahlreichen Farbgranula in den präganglionären Fasern des N. acusticus und im Bereiche des Ganglion spirale. Auch die Reissner-Membran zeichnet sich durch eine dunklere Farbe ab. Beim Versuchstier nimmt die Glukuronidase-Aktivität

Abb. 1 Nachweis der unspezifischen Esterase in der Cochlea (Kontrolltier). 590-fache Vergr.

insgesamt weniger oder gar nicht ab als dies beim Esterasenachweis beobachtet werden konnte. Am ehesten lässt sich in den inneren Haarzellen eine gewisse Reduzierung der Enzymaktivität belegen.

Man sieht eine Anhäufung von Fermentgranula im Bindegewebe des Sulcus spiralis externus (Prominentia spiralis), einem Ort, dem eine später noch zu erörternde Bedeutung zukommen dürfte. Ganz unverändert bleibt die kräftige Glukuronidase-Reaktion im N. acusticus und in den präganglionären Fasern.

Kontrollreaktionen auf die Spezifität des Enzymnachweises liessen den Schluss zu, dass hier die Aktivität der Glukuronidase nachgewiesen wurde.

4.3.3 *N-Acetyl-β-Glukosaminidase*

Beim Normaltier findet sich eine hohe Glukosaminidase-Aktivität im apikalen Anteil des

Abb. 2 Nachweis der unspezifischen Esterase in der Cochlea (Versuchstier). 590-fache Vergr.

Abb 3 Nachweis der Glukosaminidase in der Stria vascularis (Kontrolltier). 590-fache Vergr

Zytoplasmas der äusseren Haarzellen In der Stria vascularis (Abb 3) und im Zytoplasma der Ganglienzellen des Ganglion spirale Die Pfeilerzellen sind fast negativ einige Fermentkörnchen lassen sich in den Deiters- und Hensenzellen nachweisen Auch im Bereich der Prominentia spiralis ist eine deutliche Fermentaktivität festzustellen Die Membrana tectoria ist völlig frei

Im Vergleich dazu lassen die thyreoidektomierten Tiere eine Abnahme der Fermentaktivität erkennen Sie betrifft die äusseren Haarzellen die Stria vascularis (Abb 4) und die Zellen des Ganglion spirale Ziemlich unverändert bleibt der Fermentgehalt der Prominentia spiralis An den Orten die ohnehin nur eine geringe Farbreaktion im Sinne des Enzymnachweises zeigen lassen sich auch unter Versuchsbedingungen nur unwesentliche und nicht signifikante Unterschiede gegenüber den Kontrolltieren eruieren

4 3 4 *β-Galaktosidase*

Die Galaktosidase-Reaktion ist besonders stark in den Fasern des N acusticus und den vom Cortiorgan zum Ganglion spirale ziehenden Nervenfasern Im Ganglion spirale selbst ist die Reaktion überwiegend im perizellulären Bindegewebe nachzuweisen während das Zytoplasma nur einzelne Fermentgranula enthält Beim Kontrolltier erkennt man das spärlich fermentpositive Cortiorgan und die kräftiger reagierenden Nervenfasern des prägangliönären Anteils des N acusticus Fast identisch sind die Fermentreaktionen beim Versuchstier Es tritt danach keine signifikante Reduzierung der Fermente mehr ein

Neben den beschriebenen Prädilektionsstel

len, der Galaktosidase-Aktivität lässt diese sich darüberhinaus auch in der Stria vascularis, in der Reissner Membran, im Epithel des Limbus spiralis internus und externus, nicht aber in der Membrana *tectoria* nachweisen. (Tab. IV.)

Abb. 5 Nachweis der Sulfatase in der Stria vascularis (Kontrolltiere). 960-fache Vergr.

4.3.5 Aryl-Sulfatase

Die Sulfatase Reaktion fällt besonders stark in den Nervenfasern des N. acusticus (präganglionären Fasern) auf. Die Zellen des Ganglion spirale enthalten im Zytoplasma nur wenige Fermentgranula. Ausserdem erkennt man neben den positiven präganglionären Nervenfasern auch die deutliche Enzymaktivität in den inneren und äusseren Haarzellen, wobei die äusseren HZ intensiver reagieren. Auch die Stria vascularis weist zahlreiche Fermentgranula auf, die aus der Abb. 5 hervorgehen.

Die Membrana tectoria lässt keinerlei Fermentaktivität erkennen. Vergleicht man hier zu die histochemischen Reaktionen der unter Versuchsbedingungen stehenden Tiere, so kann man mit geringen Einschränkungen *feststellen*, dass die Enzymaktivitäten unverändert sind, besonders kräftige Reaktion in den Nervenfasern in der Stria vascularis.

Die Einschätzung der Fermentaktivitäten in der Cochlea des thyreoidektomierten Meerschweinchens lassen sich nach Tab. IV vornehmen.

Abb. 6. Nachweis der unspez. Esterase im Saccus endolymphaticus (Kontrolltier). 480-fache Vergr.

4.4 Nachweis der Sulfhydryle und Gesamtsulfhydryle (SH+SS) in der Cochlea

Beim Normaltier findet sich eine kräftige SH-Reaktion in den inneren und äusseren Haarzellen, in geringerem Ausmasse in den Pfeilerzellen sowie den Hensen- und Deiterszellen. Vergleiche mit der Reaktion der Gesamtsulfhydryle zeigen, dass die Farbintensität in der Stria vascularis relativ geringfügiger zunimmt als in den Zellen des sog. Stützsystems. Das Cortiorgan des Versuchstieres lässt gegenüber dem des Kontrolltieres keine auffälligen Reaktionsunterschiede erkennen. Ganz ähnlich verhält sich die Stria vascularis, die bei den meisten Versuchstieren eine starke SH-Reak-

Abb. 8. Nachweis der N-Acetyl-β-Glukosaminidase im S. e. (Kontrolltier). 480-fache Vergr.

tion aufweist, ohne dass wesentliche Reaktionsunterschiede gegenüber dem Kontrolltier auszumachen wären. Beim Vergleich von Kontroll- und Versuchstieren muss man bei der Intensität der histochemischen Reaktion davon ausgehen, dass geringfügige Quantitätsverschiebungen nur schwer eingeschätzt werden können.

4.5 Fermenthistochemische Befunde des Saccus endolymphaticus (S. e.)

4.5.1 *Unspezifische Esterase*

Beim Kontrolltier zeigt sich in der Pars intermedia eine mässig bis mittelstarke Fermentreaktion, die sich überwiegend am apikalen Pol der lumenwärts gerichteten Epithelien

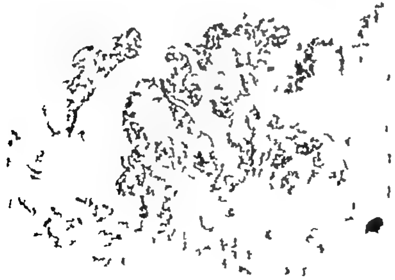

Abb. [illegible] Nachweis der N-Acetyl-Glukosaminidase im S. e. (Versuchstier). 480-fache Vergr.

-e Enzymreaktionen beim Versuchstier aus. Auch hier sind die Prädilektionsstellen des Enzyms die Epithelien der Pars intermedia und das subepitheliale Bindegewebe. Die Quantitätsschätzung der Fermente und deren Lokalisationsorte gehen aus Tab. 4 hervor.

4.6. Histochemischer Nachweis der Gluko- Mukoproteide sowie saurer Mukosubstanzen

4.6.1. PAS-Alcianblau-Reaktion nach Runge et al. (1956)

Mit dieser Färbemethode zeigt sich beim Kontroll- und Versuchstier eine intensive Anfärbung der Tectorialmembran, der Basilarmembran und deren Insertationsstellen am Limbus und Lig. spirale. Zudem wird in der bindegewebigen Grundsubstanz des Limbus spiralis eine deutliche, wenn auch schwächere Reaktion als z. B. in der Basilarmembran erkennbar.

Führt man eine Hyaluronidase-Vorbehandlung der Schnitte durch, nimmt die Anfärbbarkeit der Tectorialmembran, der Basilarmembran und des Bindegewebes von Limbus und Lig. spirale ab, d. h. es ist die Annahme berechtigt, dass an den beschriebenen Stellen saure hyaluronidasesensible Mukosubstanzen vorkommen. Durch zusätzliche Ribonukleasebehandlung wird die *Alcianophilie nicht* verändert.

Da jedoch auch nach *Hyaluronidase* Vorbehandlung in der Tectorialmembran metachromatische Reaktionen ausgelöst werden können, dürfte diese Tatsache für die Anwesenheit anderer saurer Glukoproteide sprechen, deren Existenz in letzter Zeit immer mehr in den Vordergrund gestellt wird. PAS-positives amylaseresistentes Material findet sich im Lig. und Limbus spirale, in der Tectorialmembran, Basilarmembran, in verschiedenen Zellen des Stützsystems des Cortiorgans sowie in der Stria vascularis.

Auffällige Reaktionsunterschiede bei der PAS-Alcianblau-Färbung zwischen Kontroll- und Versuchstieren existieren nicht.

Während beim Kontrolltier der Perilymphraum (Scala tympani und Scala vestibuli) sowie der Ductus cochlearis bei verschiedenen Färbemethoden färberisch „leer" ist (Abb. 10), entdeckt man bei etwa der *Hälfte aller* Versuchstiere einen Niederschlag im Perilymphraum, manchmal auch im Endolymphraum, der sich mit PAS-Alcianblau leicht blau getönt darstellt. Die Abb. 11 zeigt die Scala tympani mit einem Niederschlag bei einem Versuchstier, welches 8 Wochen zuvor thyreoidektomiert wurde. Nach Einwirkung von Hyaluronidase lassen sich zwei Farbänderungen ausmachen (Abb. 12). Einmal nimmt die Anfärbung des im Perilymphraum gelegenen Niederschlages sehr deutlich ab, zum anderen ist auch die Farbintensität der Basilarmembran, des Limbus *spiralis und des Lig.* spirale am Insertationsort der Membrana basilaris reduziert.

Bei einem anderen Tier findet sich der Niederschlag in unmittelbarer Nähe des N. acusticus (Abb. 13), wobei man den Eindruck gewinnt, dass der Nerv zur anderen Seite etwas verdrängt wird. Wendet man hier die Hyaluronidasebehandlung des Schnittes an, so erkennt *man eine auffällige Abnahme der Anfärbbarkeit des Niederschlages (Abb. 14).*

Auf Abb. 15 sieht man im Bereich des Plexus cochlearis (Balogh und Koburg, 1965) eines arteriellen und venösen Gefässnetzes in der Umgebung des N. acusticus eine Ablagerung eines alcianophilen Niederschlages, der unter dem Einfluss von Hyaluronidase stark abnimmt (Abb. 16).

Zum anderen lässt sich im Bereich des beschriebenen Plexus cochlearis ein schwach PAS-positives Material nachweisen, welches sich erwartungsgemäss unter dem Hyaluronidaseeinfluss nicht verändert, sich darüber hinaus auch in seiner morphologischen Beschaffenheit von der *hyaluronidasesensiblen Substanz in Peri-* und *Endolymphräumen* sowie im Bereich des Plexus cochlearis unterscheidet.

Zu Kontrollzwecken wurden verschiedene *Methoden* angewendet. Durch Methylierung lässt sich mit der PAS-Alcianblaufärbung keine *Blaufärbung* – weder in den verschiedenen

Tabelle V *Fermentaktivitäten in verschiedenen Bereichen des Saccus endolymphaticus nach Thyreoidektomie*

	Esterase	Glukuronidase	Glukosaminidase	Sulfatase	Galaktosidase
Epithelien Pars intermedia	+0	++	+0−+	++	+
Epithelien Pars distalis	+0	+0	+0	+	+0
Bindegewebe	0	0	0	+0	+0
Zellen im Bdg.	0	0	+0	+0	+0
Sog. freie Zellen	+0−+	+0−+	+0−++	+−++	+0

nachweisen lässt, an einzelnen Epithelabschnitten stärker als an anderen ausgeprägt ist (Abb. 6). Dabei dürfen die nur in den Epithelien vorhandenen Pigmentkörnchen nicht mit den Enzymgranula verwechselt werden. Abb. 7 stellt den S. e. eines Versuchstieres dar, bei dem lediglich (im rechten unteren Bildrand) eine nur geringe Fermentaktivität auszumachen ist. Das Bindegewebe enthält kaum Fermentkörnchen. Einzelne sog. freie Zellen in der Sacculichtung haben einen stärkeren Enzymgehalt.

4.5.2 *β-Glukuronidase*

Die Glukuronidase verhält sich hinsichtlich ihrer Aktivität in vergleichbaren Werten wie die Esterase. Beim Normaltier findet man schwache bis mittelstarke Enzymreaktionen in der Pars intermedia des S. e., weniger jedoch in der Pars distalis. Das Bindegewebe ist praktisch negativ. Einzelne sog. freie Zellen im Sacculumen sind stärker positiv. Im Vergleich hierzu verändert sich das Enzymmuster beim Versuchstier nicht.

4.5.3 *N-Acetyl-β-Glukosaminidase*

Die Glukosaminidase weist in der Pars intermedia ein beträchtliches Reaktionsprodukt auf, ebenso findet sich auch in der Pars distalis eine erhebliche Enzymaktivität. Die Abb. 8 stellt einen Ausschnitt aus der Pars rugosa (Pars intermedia des S. e.) mit dem dunkel gefärbten Epithel dar, die sich lichtmikroskopisch als blaue Fermentkörnchen abzeichnen (Kontrolltier).

Im S. e. der Versuchstiere findet sich bei den meisten eine auffällige Fermentabnahme, wie dies Abb. 9 zeigt. Man sieht die Enzymkörnchen überwiegend im apikalen, der Sacculichtung zugewandten Epithelbereich.

4.5.4 *β-Galaktosidase*

Galaktosidase und Glukuronidase verhalten sich in Enzymaktivität und Verteilungsmuster im Saccus endolymphaticus gleichermassen.

Sowohl beim Versuchstier als auch beim Kontrolltier erkennt man in den Epithelien der Pars intermedia mässige bis mittelstarke Enzymreaktionen, die in der Pars distalis deutlich geringer sind. Einzelne sog. freie Zellen in der Sacculichtung enthalten ebenfalls Fermentgranula. Das subepitheliale Bindegewebe ist praktisch negativ, abgesehen von einzelnen bindegewebigen Zellen.

4.5.5 *Nachweis der Aryl-Sulfatase*

Die Sulfatase-Reaktion fällt von allen anderen untersuchten Fermenten am stärksten aus. Wie aus den Untersuchungen hervorgeht, zeigen sich zahlreiche Fermentgranula in den Epithelien der Pars rugosa, aber auch im subepithelialen Bereich des Kontrolltieres. Das Epithel der Pars distalis ist mässig positiv. Das Saccusbindegewebe reagiert unterschiedlich stark. An manchen Stellen findet man zahlreiche mit Fermentgranula beladene Fibrozyten und Histiozyten, andererorts ist das Bindegewebe fast negativ. Zudem kommen in der Sacculichtung mit Fermentgranula beladene Zellen vor. Praktisch unverändert fallen

e Enzymreaktionen beim Versuchstier aus. uch hier sind die *Prädilektionsstellen* des nzyms die Epithelien der Pars intermedia nd das subepitheliale Bindegewebe. Die Quantitätsschätzung der Fermente und deren Lokalisationsorte gehen aus Tab. V hervor.

1.6. Histochemischer Nachweis der Gluko-/Mukoproteide sowie saurer Mukosubstanzen

1.6.1 *PAS-Alcianblau-Reaktion nach Runge et al. (1956)*

Mit dieser Färbemethode zeigt sich beim Kontroll- und Versuchstier eine intensive Anfärbung der Tectorialmembran, der Basilarmembran und deren Insertationsstellen am Limbus und Lig. spirale. Zudem wird in der bindegewebigen Grundsubstanz des Limbus spiralis eine deutliche, wenn auch schwächere Reaktion als z. B. in der Basilarmembran erkennbar.

Führt man eine Hyaluronidase-Vorbehandlung der Schnitte durch, nimmt die Anfärbbarkeit der Tectorialmembran, der Basilarmembran und des Bindegewebes von Limbus und Lig. spirale ab, d. h. es ist die Annahme berechtigt, dass an den beschriebenen Stellen saure hyaluronidasesensible Mukosubstanzen vorkommen. Durch zusätzliche Ribonukleasebehandlung wird die Alcianophilie nicht verändert.

Da jedoch auch nach Hyaluronidase-Vorbehandlung in der Tectorialmembran metachromatische Reaktionen ausgelöst werden können, dürfte diese Tatsache für die Anwesenheit anderer saurer Glukoproteide sprechen, deren Existenz in letzter Zeit immer mehr in den Vordergrund gestellt wird. PAS-positives amylaseresistentes Material findet sich im Lig. und Limbus spirale, in der Tectorialmembran, Basilarmembran, in verschiedenen Zellen des Stützsystems des Cortiorgans sowie in der Stria vascularis.

Auffällige Reaktionsunterschiede bei der PAS-Alcianblau-Färbung zwischen Kontroll- und Versuchstieren existieren nicht.

Während beim Kontrolltier der Perilymphraum (Scala tympani und Scala vestibuli) sowie der Ductus cochlearis bei verschiedenen Färbemethoden färberisch „leer" ist (Abb. 10), entdeckt man bei etwa der Hälfte aller Versuchstiere einen Niederschlag im Perilymphraum, manchmal auch im Endolymphraum, der sich mit PAS-Alcianblau leicht blau getönt darstellt. Die Abb. 11 zeigt die Scala tympani mit einem Niederschlag bei einem Versuchstier, welches 8 Wochen zuvor thyreoidektomiert wurde. Nach Einwirkung von Hyaluronidase lassen sich zwei Farbänderungen ausmachen (Abb. 12): Einmal nimmt die Anfärbung des im Perilymphraum gelegenen Niederschlages sehr deutlich ab, zum anderen ist auch die Farbintensität der Basilarmembran, des Limbus spiralis und des Lig. spirale am Insertationsort der Membrana basilaris reduziert.

Bei einem anderen Tier findet sich der Niederschlag in unmittelbarer Nähe des N. acusticus (Abb. 13), wobei man den Eindruck gewinnt, dass der Nerv zur anderen Seite etwas verdrängt wird. Wendet man hier die Hyaluronidasebehandlung des Schnittes an, so erkennt man eine auffällige Abnahme der Anfärbbarkeit des Niederschlages (Abb. 14).

Auf Abb. 15 sieht man im Bereich des Plexus cochlearis (Balogh und Koburg, 1965) eines arteriellen und venösen Gefässnetzes in der Umgebung des N. acusticus eine Ablagerung eines alcianophilen Niederschlages, der unter dem Einfluss von Hyaluronidase stark abnimmt (Abb. 16).

Zum anderen lässt sich im Bereich des beschriebenen Plexus cochlearis ein schwach PAS-positives Material nachweisen, welches sich erwartungsgemäss unter dem Hyaluronidaseeinfluss nicht verändert, sich darüberhinaus auch in seiner morphologischen Beschaffenheit von der hyaluronidasesensiblen Substanz im Peri- und Endolymphräumen sowie im Bereich des Plexus cochlearis unterscheidet.

Zu Kontrollzwecken wurden verschiedene Methoden angewendet. Durch Methylierung lässt sich mit der PAS-Alcianblaufärbung keine Blaufärbung – weder in den verschiedenen

Tabelle V *Fermentaktivitäten in verschiedenen Bereichen des Saccus endolymphaticus nach Thyreoidektomie*

	Esterase	Glukuro-nidase	Glukosa-minidase	Sulfa-tase	Galakto-sidase

4.6. Histochemischer Nachweis der Gluko-Mukoproteide sowie sauren Mukosubstanzen

4.6.1 *PAS-Alcianblau-Reaktion nach Runge et al (1956)*

Mit dieser Farbemethode zeigt sich beim Kontroll- und Versuchstier eine intensive Anfärbung der Tectorialmembran der Basilarmembran und deren Insertationsstellen am Limbus und Lig. spirale Zudem wird in der bindegewebigen Grundsubstanz des Limbus spiralis eine deutliche wenn auch schwächere Reaktion als z.B in der Basilarmembran erkennbar

Führt man eine Hyaluronidase-Vorbehandlung der Schnitte durch nimmt die Anfärbbarkeit der Tectorialmembran, der Basilarmembran und des Bindegewebes von Limbus und Lig. spirale ab d h es ist die Annahme berechtigt dass an den beschriebenen Stellen saure hyaluronidasesensible Mukosubstanzen vorkommen. Durch zusätzliche Ribonukleasebehandlung wird die Alcianophilie nicht verändert.

Da jedoch auch nach Hyaluronidase-Vorbehandlung in der Tectorialmembran metachromatische Reaktionen ausgelöst werden konnen durfte diese Tatsache fur die Anwesenheit anderer saurer Glukoproteide sprechen deren Existenz in letzter Zeit immer mehr in den Vordergrund gestellt wird PAS-positives amylaseresistentes Material findet sich im Lig und Limbus spirale in der Tectorialmembran Basilarmembran in verschiedenen Zellen des Stützsystems des Cortiorgans sowie in der Stria vascularis

Auffällige Reaktionsunterschiede bei der PAS-Alcianblau-Farbung zwischen Kontroll- und Versuchstieren existieren nicht.

Wahrend beim Kontrolltier der Perilymphraum (Scala tympani und Scala vestibuli) sowie der Ductus cochlearis bei verschiedenen Färbemethoden färberisch „leer" ist (Abb 10) entdeckt man bei etwa der Hälfte aller Versuchstiere einen Niederschlag im Perilymphraum, manchmal auch im Endolymphraum der sich mit PAS-Alcianblau leicht blau getönt darstellt. Die Abb 11 zeigt die Scala tympani mit einem Niederschlag bei einem Versuchstier welches 8 Wochen zuvor thyreoidektomiert wurde. Nach Einwirkung von Hyaluronidase lassen sich zwei Farbänderungen ausmachen (Abb 12) Einmal nimmt die Anfärbung des im Perilymphraum gelegenen Niederschlages sehr deutlich ab zum anderen ist auch die Farbintensität der Basilarmembran des Limbus spiralis und des Lig. spirale am Insertationsort der Membrana basilaris reduziert.

Bei einem anderen Tier findet sich der Niederschlag in unmittelbarer Nähe des N acusticus (Abb 13) wobei man den Eindruck gewinnt dass der Nerv zur anderen Seite etwas verdrängt wird Wendet man hier die Hyaluronidasebehandlung des Schnittes an, *so erkennt man eine auffällige Abnahme der* Anfärbbarkeit des Niederschlages (Abb 14)

Auf Abb 15 sieht man im Bereich des Plexus cochlearis (Balogh und Koburg, 1965) eines arteriellen und venösen Gefässnetzes in der Umgebung des N acusticus eine Ablagerung eines alcianophilen Niederschlages der unter dem Einfluss von Hyaluronidase stark abnimmt (Abb 16)

Zum anderen lässt sich im Bereich des beschriebenen Plexus cochlearis ein schwach PAS-positives Material nachweisen welches sich erwartungsgemäss unter dem Hyaluronidaseeinfluss nicht verändert, sich darüberhinaus auch in seiner morphologischen Beschaffenheit von der hyaluronidasesensiblen Substanz in Peri und Endolymphräumen sowie im Bereich des Plexus cochlearis unterscheidet.

Zu Kontrollzwecken wurden verschiedene Methoden angewendet. Durch Methylierung lässt sich mit der PAS-Alcianblaufärbung keine Blaufärbung — weder in den verschiedenen

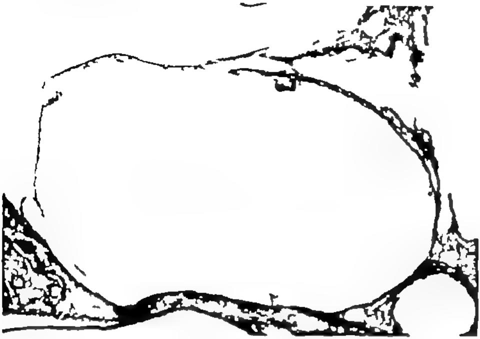

Abb 10 PAS-Alcianblau-Reaktion der Scala tympani (Kontrolltier). 150-fache Vergr

Gewebsbereichen noch in den Niederschlägen – erzielen Durch Sulfatierung wird keine vermehrte Blaufärbung erreicht Bei Hyaluronidase Vorbehandlung nimmt – wie schon mehrfach erwähnt – die Anfärbbarkeit der Basilarmembran der Tectorialmembran und des Limbus spiralis sowie des Lig. spirale ab Ein ähnliches Verhalten wenn auch in stärkerem Ausmasse lassen die Niederschläge im Peri und Endolymphraum erkennen Bei der Ribonuklease Anwendung kann man lediglich im Zytoplasma der Ganglienzellen eine starke Verringerung der Anfärbbarkeit auslösen

4 6 2 Eisenbindungsreaktion nach Hale (1946) in der Modifikation nach Graumann und Clauss (1958) oder PAS Hale nach Ritter und Oleson (1950)

Basilarmembran und deren Ansatzstellen am Limbus spiralis und Lig. spirale sowie die Tectorialmembran färben sich intensiv an

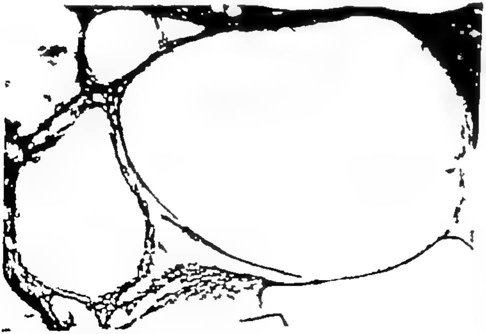

Abb 11 PAS-Alcianblau Reaktion der Scala tympani ohne Hyaluronidase Vorbehandlung (Versuchstier) 150-fache Vergr

Abb. 12 PAS-Alcianblau-Reaktion der Scala tympani desselben Versuchstieres wie Abb. 11 mit Hyaluronidase Vorbehandlung. 150-fache Vergr.

ähnlich verhält sich auch die Stria vascularis. Der Limbus spiralis weist eine kräftigere Reaktion im Bereiche der Huschkeschen Hörzähne auf. Das Cortiorgan ist negativ. Auch bei dieser Methode finden sich keine ins Gewicht fallenden Farbunterschiede zwischen Kontroll- und Versuchstier.

Vergleichbar jedoch der Alcianblaufärbung lassen sich auch in den Skalen und im Bereich des Plexus cochlearis Niederschläge aufzeigen, deren Anfärbbarkeit unter dem Einfluss von Hyaluronidase abnimmt, d. h. also, dass hier ein hyaluronidasesensibles Substrat vorliegt. Ribonuklease-Behandlung des Schnittes beeinflusst die Farbintensität nicht.

4.6.3 *Metachromasie-Reaktionen*

4.6.3.1 *Azur-A bei verschiedenen pH Werten*

Wie aus der Tabelle Nr. 6 hervorgeht, sieht man in der Cochlea bei pH 4,5 eine starke

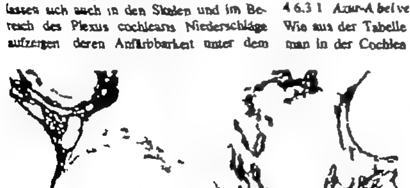

Abb. 13 PAS-Alcianblau-Reaktion in Nähe des N. acusticus ohne Hyaluronidasebehandlung (Versuchstier). 150-fache Vergr.

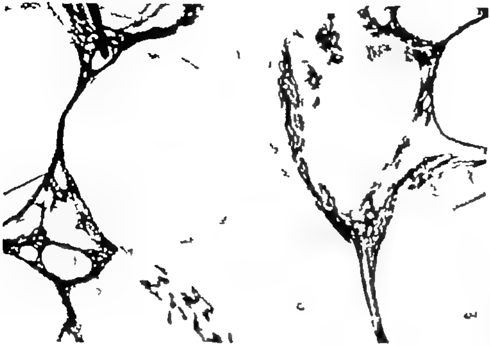

Abb 14 PAS-Alcianblau Reaktion desselben Versuchstieres wie in Abb 13 mit Hyaluronidasebehandlung 150-fache Vergr

Metachromasie Reaktion der Tectorialmembran der Basilarmembran und des Knochens des Modiolus Auch das Verankerungssystem der Basilarmembran im Limbus spiralis und Lig spirale reagieren metachromatisch ebenso eine dreieckige Zone oberhalb des Ansatzes der Basilarmembran am Lig. spirale Das Cortiorgan und die tympanale Belegschicht lassen sich nur orthochromatisch anfärben Die Reissner Membran reagiert schwach metachromatisch die beschriebenen Niederschläge in den Skalen im Ductus cochlearis sowie im Bereich des Plexus cochlearis der Versuchstiere verhalten sich weitgehend orthochromotrop

Bei pH 3 tritt ein Farbumschlag der Niederschläge ein d h bei diesem pH Wert wird *eine Metachromasie Reaktion* ausgelöst Im übrigen verhalten sich auch bei diesem pH Wert die Tectorialmembran die Basilarmem-

=Großteils unspezifische Rötung

bran und deren Verankerungssystem sowie der Knochen im Modiolus deutlich metachromatisch. Cortiorgan und Stria vascularis sowie die tympanale Belegschicht zeigen nur Orthochromasie.

Bei *pH 1,5* treten in der Cochlea fast nur orthochromatische Reaktionen auf.

Durch Ribonuklease Vorbehandlung der Schnitte wird die Metachromotropie des Gewebes nicht auffällig verändert. Durch Hyaluronidase lässt sich eine geringfügige Abnahme der Metachromotropie in der Tectorialmembran ausmachen. In stärkerem Ausmasse lässt der metachromatische Effekt in den alcianophilen Niederschlagen der Versuchstiere nach.

4.6.3.2 *Toluidinblau bei abgestuften CaCl-Konzentrationen* Bei 0,04 M Toluidinblau-Lösung erkennt man keine Metachromasie, es fällt lediglich eine unspezifische Rotfärbung fast aller Cochleastrukturen auf.

Mit der 0,1 M Lösung zeigen sich gleichfalls noch keine auffälligen Farbumschläge in den verschiedenen Innenohrstrukturen, was auf eine Metachromasie Reaktion schliessen lassen könnte. Bei den Versuchstieren verhalten sich die beschriebenen Niederschläge orthochromatisch.

Erst bei 0,2 M Toluidinblau Lösung kann man Metachromasie-Reaktionen feststellen, wie sie sich etwa bei der Azur A Färbung pH 3,5 beobachten lassen. Tectorialmembran und Basilarmembran färben sich rot an, eben so verhalten sich die bindegewebigen Areale des Verankerungssystems der Basilarmembran. Cortiorgan, tympanale Belegschicht, Reissner Membran, Stria vascularis verhalten sich orthochromatisch. Im Vergleich dieser Innenohrstrukturen ergeben sich keine bemerkenswerten Unterschiede zwischen Kontroll- und Versuchstier.

Die nur bei den Versuchstieren zu beobachtenden Niederschläge in den Skalen im Bereich des Plexus cochlearis lassen eine eindeutige Metachromasiereaktion erkennen. Sie stellen sich bei der 0,3 M Lösung rot dar.

Abb 16 PAS-Alcianblau-Reaktion desselben Versuchstieres mit Hyaluronidasebehandlung, 140-fache Vergr

Als Kontrollreaktionen wurden die gleichen Verfahren angewendet wie bei der Azur A Methode (Hyaluronidase Ribonuklease) Die verschiedenen Metachromasieresultate sind der Tab VI zu entnehmen

4 7 Histochemischer Nachweis der Gluko-Mukoproteide sowie sauren Mukosubstanzen im Saccus endolymphaticus

4 7 1 *PAS Alcianblau Reaktion nach Runge et al (1956)*

Mit dieser Methode lässt sich eine mittelstarke Reaktion im Bindegewebe besonders im subepithelialen Bereich der Pars intermedia (Pars rugosa) des Normaltieres darstellen Ebenso färbt sich das Zytoplasma einzelner grösserer Bindegewebszellen an Das Epithel verhält sich praktisch negativ Bei dem Normaltier färbt sich der Inhalt des Saccus endolymphaticus mit der PAS Alcianblau Reaktion kaum oder gar nicht an während er sich bei der Hämatoxilin Eosin Anfärbung schwach rot darstellt. Bei einigen Versuchstieren lässt sich ein Saccusinhalt beobachten der sich mit PAS Alcianblau schwach blau darstellt Ausser diesem alcianophilen Saccusinhalt besteht kein signifikanter Farbunterschied in den einzelnen Strukturen des Saccus endolymphaticus zwischen Kontroll und Versuchstier

Wendet man zu Kontrolluntersuchungen Hyaluronidasebehandlung des Schnittes an so zeigt sich dass der Inhalt des Saccuslumen z T hyaluronidasesensibel ist d h die Anfärbbarkeit des Materials herabgesetzt wird Unter Ribonuklease Einwirkung wird das Zytoplasma der Bindegewebszellen praktisch farblos darüberhinaus ändert sich der Farbton der alcianblaupositiven Substanzen nicht

4 7 2 *Eisenbindungsreaktion nach Hale (1946) in der Modifikation nach Graumann und Clauss (1958) oder PAS Hale nach Ritter und Oleson (1950)*

Hier ergeben sich praktisch die gleichen Ergebnisse wie bei der PAS-Alcianblaufärbung Es färbt sich in besonderem Masse das Bindegewebe des S e an was besonders im subepithelialen Bereich der Pars intermedia in Erscheinung tritt Das Epithel ist kaum angefärbt schwach reagiert das Zytoplasma ein

zelner sog. freier Zellen in der Saccusschichtung. Bei einigen Versuchstieren färbt sich auch der Inhalt des Saccus leicht an. Der Farbton verschwindet unter dem Einfluss von Hyaluronidase weitgehend. Bei anderen Versuchs- und Kontrolltieren wird der schwach blau gefärbte Saccusinhalt durch Hyaluronidase in seiner Anfärbbarkeit nicht beeinflusst.

Abb 16 PAS-Alcianblau Reaktion desselben Versuchstieres mit Hyaluronidasebehandlung. 150-fache Vergr

Als Kontrollreaktionen wurden die gleichen Verfahren angewendet wie bei der Azur A Methode (Hyaluronidase Ribonuklease) Die verschiedenen Metachromasieresultate sind der Tab VI zu entnehmen

4 7 Histochemischer Nachweis der Gluko-Mukoproteide sowie sauren Mukosubstanzen im Saccus endolymphaticus

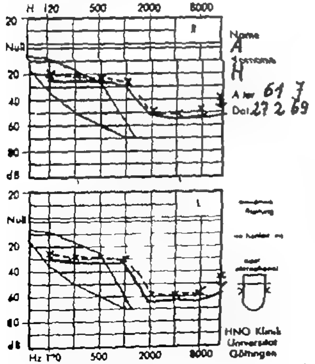
5 Eigene klinische Beobachtung von hypothyreotisch bedingten Hörstörungen

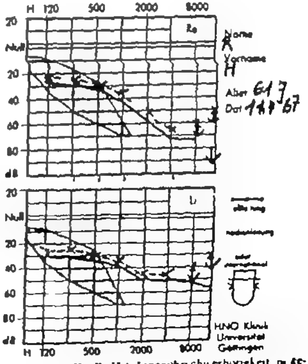
In der Poliklinik der Hals-Nasen-Ohrenklinik Göttingen konnten wir in der letzten Zeit zwei Patienten untersuchen, die an einer Unterfunktion der Schilddrüse in Verbindung mit einer rasch zunehmenden Hörstörung litten.

Bei einem 61jährigen Patienten (H. A.) stellte sich 3–4 Monate zuvor eine zunehmende Heiserkeit ein; gleichzeitig bemerkte er ein deutliches Nachlassen des Hörvermögens. Bei der Untersuchung in der Medizinischen Klinik in Göttingen wurde die Diagnose „Myxoedem bei einer Hashimoto-Thyreoiditis" gestellt. Die Untersuchung der Ohren erbrachte bds. völlig reizlose Trommelfelle, die Tubenfunktion war regelrecht. Die elektronakustische Hörprüfung zeigte eine beiderseitige Innenohrstörung, wobei hauptsächlich die hohen Frequenzen (1000–8000 Hz) betroffen waren. Die ohrenärztliche Diagnose lautete: Schallempfindungsstörung bds. bei Unterfunktion der Schilddrüse.

Eine 61jährige (R. H.) bemerkte seit über 1 Jahr eine „Schwellung der Haut", Müdigkeit, Konzentrationsschwäche. Ausserdem stellte sie eine immer mehr zunehmende Schwerhörigkeit fest. Die Pat. wurde wegen einer primären Hypothyreose stationär behandelt und zur Überprüfung des Hörvermögens der Hals-Nasen-Ohrenklinik vorgestellt. In der Anamnese gab sie an, bis vor 1 Jahr gut gehört zu haben; gleichzeitig, mit Zunahme der Hautschwellung, habe sich das Gehör immer mehr verschlechtert. Die otoskopische Untersuchung ergab völlig reizlose, intakte Trommelfelle. Die elektroakustische Hörprüfung zeigte eine beiderseitige Innenohrstörung im gesamten Frequenzbereich, die links etwas stärker als rechts ausgeprägt war. Diagnose: Bds. Schallempfindungsstörung bei Unterfunktion der Schilddrüse.



Audiogramm I (H. A.) Innenohrschwerhörigkeit bds., besonders im Hochtonbereich.



Audiogramm II (R. H.) Innenohrschwerhörigkeit im gesamten Frequenzbereich links stärker als rechts.

6 Hörstörungen in Verbindung mit Schilddrüsenerkrankungen

6.1 Endemischer Kretinismus und Pendred-Syndrom

Zahlreiche Publikationen aus der Mitte des vorigen Jahrhunderts bis in die jüngste Zeit haben sich mit der Frage nach dem *Funktionszusammenhang zwischen Schilddrüse und Ohr* beschäftigt. Nach Kenntnis der Literatur kann man sich jedoch nicht des Eindruckes erwehren, dass die möglichen Zusammenhänge eher unübersichtlich und in ihrer Interpretation recht verschiedenartig dargestellt sind. Im folgenden soll daher ein kurzer Überblick über die Schilddrüsenerkrankungen gegeben werden, die mit Hörstörungen einhergehen können oder bei denen die Schwerhörigkeit obligater Bestandteil der Erkrankung ist.

Seit langem ist bekannt, dass die bei endemischen Kretinen zu beobachtende Schwerhörigkeit oder Taubstummheit häufig vorkommt, ohne jedoch obligates Symptom der Schilddrüsenerkrankung zu sein. Ebenso ist die Verbreitung von Gehörstörungen nicht gleichzusetzen mit der Häufigkeit des endemischen Kretinismus oder der Intensität der Kropfendemien (Trotter, 1960; Greenwald, 1960; Costa und Ferrara, 1963). *Nach Dannowski (1962) haben 35% der Kretins eine* nicht reversible Schwerhörigkeit bis Taubstummheit.

Manche Autoren bestreiten überhaupt einen direkten Zusammenhang zwischen der Schilddrüse und dem Ohr. Sie führen hierfür als Beweis an, dass Kinder mit angeborener Hypothyreose fast nie eine Hörstörung aufweisen. Sie stehen damit im Gegensatz zu *Prader (1957)*, der bei kindlichen Hypothyreosen häufiger *eine gewisse Schwerhörigkeit* feststellte. Letztlich muss betont werden, dass die Gehörstörungen beim endemischen Kretinismus durch Hormonsubstitution nicht zu beseitigen sind.

Zahlreiche *pathologisch-anatomische Arbeiten befassen sich mit dem Hörorgan von endemischen Kretins*, deren Ergebnisse auf eine Schalleitungsstörung schliessen lassen müssten (Siebenmann, 1904; Manasse, 1909; Schlittler, 1917; Nager, 1917; Mayer, 1919; Oppikofer, 1921; Steurer, 1922*a*, *b*). Die meisten audiologischen Untersuchungsergebnisse, soweit sie bei den oft debilen Patienten auszuwerten sind, deuten aber auf einen schweren Innenohrschaden und weniger häufig auf eine Schalleitungsschwerhörigkeit hin (Lüscher, 1948; König, 1968 u. a.). Als pathologisches *Substrat der Schwerhörigkeit* wurden *Verengerung der Fensternischen, Verklumpung der Gehörknöchelchen*, Verdickung der Paukenschleimhaut und schlecht pneumatisierte Warzenfortsätze angegeben. Andere und dieselben Autoren wie Siebenmann (1906), Denker (1909), Alexander (1909, 1919), Oppikofer (1913), Habermann (1909), Brock (1920) und Nager (1921) fanden bei entsprechenden Autopsien keine Mittel- oder Innenohrveränderungen. Wegen der Schwierigkeit der Durchführung von elektroakustischen *Hörprüfungen* bei den oftmals oligophrenen Patienten ist es nicht verwunderlich, wenn bislang nur relativ wenig entsprechende *Untersuchungen gemacht* wurden. Versucht man eine zusammenfassende Darstellung der Hörstörungen in Verbindung *mit dem endemischen Kretinismus zu geben*, lassen sich vielleicht folgende Gesichtspunkte herausstellen:

a) Die Gehördefekte *kommen fast nur in* Gebieten mit endemischem Kretinismus vor und stellen eines der regelmässigsten Symp*tome im Ablauf* dieser Erkrankung dar.

b) Kropf-Endemien mit endemischem Kreti-

nismus werden meist in abgelegenen Gegenden beobachtet. Daher ist es infolge Inzucht durchaus möglich dass eine nicht durch den endemischen Kretinismus bedingte Taubstummheit vermehrt auftreten kann (Hanhart 1924 Secrétan 1954 Clements 1958)

c) König weist darauf hin dass rezessive nicht endemische Formen der kongenitalen Taubstummheit das *Pendred Syndrom sowie* Embryopathien (Rubeolen) als Ursache für die Hörstörung berücksichtigt werden müssen wenn man Zusammenhänge zwischen dem endemischen Kretinismus und ihn begleitender Hörstörungen beurteilen will

d) Die Häufigkeit der Hörstörung als *Symptom des endemischen Kretinismus* wechselt von Endemiegebiet zu Endemiegebiet was aus den Untersuchungen von McCarrison (1908) Greenwald (1960) McCullagh (1963) Srinivasan et al (1964) sowie Choufoer et al (1965) hervorgeht

Eine weitere Schilddrüsenerkrankung die *in Verbindung mit einer oft sehr erheblichen Innenohrstörung auftritt* ist das sog Pendred Syndrom ein autosomal rezessiv vererbbares Leiden Der Grad der Schwerhörigkeit und das Ausmass des Kropfes sind unterschiedlich Nach Fraser (1964) liegt eine progressive Schallempfindungsstörung vor deren Ursache *in der Cochlea zu lokalisieren* ist und die zumeist die hohen Tonfrequenzen betrifft Die Schilddrüsenstörung beruht auf einem *Defekt* der Jodoxydation im Sinne einer Jodverwertungsstörung die man auch bei anderen Schilddrüsenerkrankungen beobachten kann Die Hypothyreose ist häufig nicht sehr deutlich ausgeprägt

6 2 Primare Hypothyreose infolge quantitativer Störung der Hormonbildung

Ebenfalls ist eine *Hörstörung bei Patienten* mit erworbener Hypothyreose bekannt Durch Hormonsubstitution lässt sich oftmals das Hörvermögen bessern bzw normalisieren Die Art der Schwerhörigkeit und die Häufigkeit des Auftretens bei erworbener Hypothyreose wird von den Autoren recht unterschiedlich beurteilt. King (1907) beschrieb eine intermittierende Hypothyreose bei einem Erwachsenen mit rezidivierender Schwerhörigkeit die sich durch Hormonsubstitution besserte Mutmasslich handelte es sich um eine Innenohrstörung.

Kemp (1907) stellte bei einem Erwachsenen mit einer im späteren Lebensalter erworbenen Unterfunktion der Schilddrüse eine Schwerhörigkeit fest die er auf ein verdicktes Trommelfell bezieht Durch Hormonsubstitution besserte sich das Gehör

Unter 3 hypothyreotischen Patienten fand *Kellner (1922) einen Kranken mit Schwerhörigkeit* die er als eine Schalleitung diagnostizierte und auf ein Myxoedem der Paukenschleimhaut bezog.

Moehlig (1927) beschreibt erstmals hypothyreotische Patienten die an einer leider nicht näher klassifizierten Schwerhörigkeit in *Kombination mit Schwindelzuständen litten. Er konnte diese Störung bei 24 Patienten* nachweisen Als Erklärung erwägt der Autor einen Hydrops des Labyrinthes ähnlich wie beim Morbus Menière ohne jedoch nähere Angaben über die Gründe seiner Vermutung zu machen

Drury (1927) berichtete über 2 Patienten mit Hypothyreose die an einer Schwerhörigkeit litten *Um welche Form der Schwerhörigkeit* es sich handelte wird nicht angegeben

Von 6 Kranken mit Hypothyreose litt nach den Angaben von Mann *(1929)* nur einer an einer Schallempfindungsstörung die sich zudem noch einseitig manifestierte. Auf Hormonsubstitution indessen besserte sich die Hypacusis

1931 berichtete der gleiche Autor über 4 *weitere Fälle mit* Myxoedem und Hörstörung In dieser Publikation ist nur von einem Patienten *mit Hörstörung die Rede*

McLaurien (1945) betont dass er bei einem hypothyreotischen *Patienten eine Hörstörung* bemerkte die sich durch keinen krankhaften Befund am Trommelfell *erklären liess* Leider

verabsäumte auch dieser Autor eine audiometrische Untersuchung.

Barnes (1947) untersuchte über 45 Myxoedemkranke, die angeblich alle eine Schalleitungsstörung aufwiesen. Aus dieser Arbeit gehen keine näheren Angaben über otoskopische Befunde hervor.

Marquet (1956) nimmt eine langsame Entstehung der Hörstörung bei erworbenen Hypothyreosen an und führt deren Entstehung auf ein „Oedem zwischen den Zellen" zurück. In dieser Arbeit wird nicht streng zwischen der Hörstörung beim endemischen Kretin und der Hörstörung des später hypothyreotisch gewordenen Patienten getrennt. Nach Angaben von Marquet (1956) lag zumeist eine Schallempfindungsstörung vor.

Hilger (1956) veröffentlichte die Krankengeschichten von 4 hypothyreotischen Patienten, von denen drei an einer Schallempfindungsstörung und einer an einer Schalleitungsstörung litt. Das Hörvermögen war nach den audiometrischen Untersuchungen im gesamten Frequenzbereich gestört. Nach Hormonsubstitution erfolgte eine Besserung des Hörvermögens, was auch audiometrisch belegt werden konnte.

Howarth und Lloyd (1956) hatten 7 hypothyreotische Patienten untersucht und fanden 5 mit einer Schallempfindungsstörung und 2 mit einer Schalleitungsstörung. Bei 6 Patienten besserte sich das *Hörvermögen* durch Hormonsubstitution.

Die grösste *Anzahl* von hypothyreotischen Patienten mit Hörstörungen untersuchten Nickel und Frame (1958). 31 ihrer 100 Kranken liessen eine Schwerhörigkeit erkennen, über deren Art jedoch keine näheren Angaben gemacht werden.

Ritter und Lawrence (1960) untersuchten einen Patienten, der durch hohe Thiouracilgaben hypothyreotisch geworden war, und einen zweiten, der an einer primären idiopathischen Hypothyreose litt. Bei beiden Patienten bestand eine Schallempfindungsstörung, *die* durch Hormonsubstitution gebessert *werden* konnte.

De Vos (1963) berichtete in einer längeren sehr sorgfältig durchgeführten Arbeit über 37 Kranke mit erworbener Hypothyreose, von denen 10 eine Schwerhörigkeit vom Typ der Schallperzeptionsstörung aufwiesen. Aus dem Fehlen des Recruitmentphänomens schloss de Vos, dass das Cortiorgan als Ursprungsort für die Schwerhörigkeit auszuschliessen ist. Durch Hormongaben konnte er keine auffällige Besserung des Hörvermögens erzielen.

Post (1964) verfolgte die Krankheitsverläufe von 47 hypothyreotischen Patienten. Unter diesen Kranken gaben lediglich 4 eine Hörstörung an. *Drei* weitere Patienten mit einer Lärmschädigung des Innenohres und 3 mit einer bereits vor dem Auftreten der Hypothyreose diagnostizierten Schallempfindungsstörung wiesen keine weitere Verschlechterung des Hörvermögens auf.

Dennhardt (1965) behandelte 2 Patienten, bei denen neben einer Unterfunktion der Schilddrüse mit Myxoedem eine audiometrisch nachgewiesene Schalleitungsstörung vorlag. Diese Schwerhörigkeit besserte sich durch Hormongaben.

Stellt man die mitgeteilten Kasuistiken in einer Tabelle zusammen (Tab. Nr. 7), so gewinnt man den Eindruck einer gewissen Uneinheitlichkeit in dem klinischen Untersuchungsergebnis zum Problem erworbene Hypothyreosen – Hörstörung. Bei den aufgeführten Patienten hatte sich aus verschiedenen Gründen die Hypothyreose im Jugend- oder Erwachsenenalter manifestiert. Man darf wohl davon ausgehen, dass eine *primäre* Hypothyreose vorlag. Von den insgesamt 275 Patienten litten 141 an einer Schwerhörigkeit, deren Einteilung in *die* Schalleitungs- und Schallempfindungsstörung leider *nicht* von allen Autoren berücksichtigt wurde. Die Publikation von *Barnes (1947)* – er hatte bei 45 hypothyreotischen Patienten 45 Schalleitungsstörungen *festgestellt* – muss wohl mit Zurückhaltung beurteilt werden, da er keine genauen *otoskopischen* Befunde anführt. Seine Angaben stehen auch in einem Widerspruch zu allen anderen Autoren, wie aus Tab. 7 er-

Tabelle VII *Zusammenstellung der in der Literatur mitgeteilten Fälle von hypothyreotisch bedingter Schwerhörigkeit (primäre Hypothyreose)*

Autoren	Fälle mit erworbener Hypoth	Schallempfindungsstörung	Schalleitungsstörung	Nicht näher def Schwerhörigkeit
Kemp (1907)	1	1		
King (1907)	1	1		
Keßner (1922)	3		1	
Moehlig (1927)	4			4
Drury (1937)				
Mann (1929)	6	1 (einseitig)		
Mann (1931)	4		1	
Mc Laurien (1945)	1			1
Barnes (1947)	45		45(1)	
Rau (1947)	1	1		
Hilger (1956)	4	3	1	
Howarth+Lloyd (1956)	7	6		
Nickel+Frame (1958)	100			31
Ritter+Lawrence (1960)	2			
De Vos (1963)	3	15		
Post (1964)	4	3		
Dennhard (1965)				

sichtlich ist Ohne Berücksichtigung der Arbeit von Barnes (1947) und der Publikationen in denen die Form der Hörstörung nicht mitgeteilt wurde erhält man ein Verhältnis Schallempfindungsstörung / Schalleitungsstörung von 33 7 bei insgesamt 129 hypothyreotischen Patienten Diese Zahl stimmt in etwa mit den Angaben von Means (1948) überein der bei der primären erworbenen Hypothyreose 30% Schwerhörigkeit feststellte

Hinsichtlich der Entstehung der hypothyreotisch bedingten Schwerhörigkeit werden folgende Ansichten geäussert

McMahon (1947) nimmt eine durch den Thyroxinmangel hervorgerufene Minderung der Resistenz gegenüber Infektionen an woraus sich Otitiden und Tubenkatarrhe entwikkeln können Aus einem solchen Befund könnte eine Schalleitungsstörung resultieren Bei der Herabsetzung der Schallempfindung diskutiert der Autor eine zentrale Schädigung hält jedoch auch einen Hydrops der Schnecke für möglich Marquet (1956) betont das Fehlen des Recruitmentphänomens bei der hypothyreotischen Innenohrstörung und leitet daraus ab dass ursächlich eine Alteration des Cortiorgans nicht in Frage kommen kann Die Schwerhörigkeit entsteht nach Ansicht des Autors durch ein Ödem zwischen den Zellen mutmasslich zwischen den Zellen des Ganglion spirale Marquet führt 3 Gesichtspunkte an a) durch den Schilddrüsenmangel kommt es zu einer ödematösen Infiltration des endolymphatischen Kreislaufes und dadurch zu einer Perineuritis des Hörnerven (=typische Schallempfindungsstörung) b) Myxomatöse Läsionen im Mittelohr (=Schalleitungsstörung) c) Minderung des zentralen Hörvermögens

Ritter und Lawrence (1960) erwägen als Ursache für die Schwerhörigkeit eine durch den Thyroxinmangel ausgelöste ödematöse cochleare Veränderung wie sie auch in ähnlicher Weise von Marquet (1956) in den Vordergrund gestellt wird

De Vos (1963) kommt auf Grund seiner klinischen und experimentellen Arbeiten zu dem Ergebnis dass die hypothyreotisch bedingte Schwerhörigkeit auf einer Störung im Bereich des Ganglion spirale mit einer zusätzlich möglichen cerebralen Beeinträchtigung beruht Auch er betont das Fehlen des Recruitmentphänomens (wie Marquet 1956) und leitet daraus den Schluss ab dass eine direkte Schä

digung des Cortiorgans nicht in Betracht gezogen werden kann, sondern vielmehr im Bereich des Ganglion scarpae und des N. acusticus zu suchen ist.

Post (1964) hält cochleäre Ursachen für die Schallempfindungsstörung möglich, betont darüberhinaus, dass nach seinen klinischen Untersuchungen keine spezifische Verbindung zwischen dem Alter der Kranken, dem Grad der Hypothyreose und der daraus resultierenden Schwerhörigkeit existiert. Manche Patienten mit schwerer Hypothyreose haben keine Schwerhörigkeit, andere mit leichter Schilddrüsenunterfunktion eine sehr deutliche Schallempfindungsstörung.

Letztlich erwägt Dennhardt (1965) eine durch die Hypothyreose verursachte Verschiebung von Glukoproteiden und sauren Mukopolysacchariden im Innenohr, obwohl die von ihm beobachteten hypothyreotischen Patienten an einer Schalleitungsstörung litten.

Die angeführten Vorstellungen zur Genese der hypothyreotischen Schwerhörigkeit sind zumeist weitgehend unbewiesen und beruhen auf Analogieschlüssen, sieht man von ganz wenigen, später noch anzuführenden experimentellen Arbeiten (Poulsen, 1959; de Vos, 1963; Ritter, 1967) ab. Alle angeführten Denkmodelle erscheinen einleuchtend, wenn es sich um die Erklärung der Schalleitungsstörung handelt. Die Schallempfindungsstörungen stossen jedoch hinsichtlich ihrer Interpretation auf wesentlich grössere Schwierigkeiten.

7 Grundlagen zur Synthese, Produktion, Wirkungsweise und biologischen Wirkung der Schilddrüsenhormone

Die Hauptaufgabe der Schilddrüse besteht in der Synthese und Inkretion der beiden Hormone L Thyroxin und L Trijodthyronin Für die Synthese der Schilddrüsenhormone wird das Spurenelement Jod benötigt welches als ionales Jod im Blut entnommen und in eine besondere organische Bindung eingebaut wird Das entstandene Produkt muss danach gespeichert und im Bedarfsfall in Aminosäureform abgegeben werden können Der thyreoidale Jodumsatz stellt die spezielle Leistung der Schilddrüse dar Er verläuft in 5 Phasen die in Anlehnung an Klein (1969) summarisch wiedergegeben werden sollen

a) Jodination d h Jodanreicherung aus dem Blut im Schilddrüsengewebe

b) Jodisation d h Jodierung des in der Follikelzelle und im Kolloid vorhandenen Tyrosin zu sog. inaktiven Hormonvorläufern (Tyrosin zu 3 Monojodtyrosin 3-Mono- zu 3,5-Dijodtyrosin)

c) Koppelung von Jodtyrosin zu Jodthyroxin

d) Das Jodthyreoglobulin des Kolloids stellt das thyreoidale Jodreservoir dar Es enthält sämtliche organische Jodverbindungen der Schilddrüse ca $^1/_4$ bis $^1/_3$ Anteil Tyrosin mit nur geringen Mengen von Trijodthyroxin

e) Hormoninkretion durch Proteolyse des Thyreoglobulins durch eine Schilddrüsenprotease Thyroxin und Trijodthyronin verlassen in Aminosäureform die Schilddrüse

Nach neueren Forschungen kann als gesichert gelten dass die Schilddrüsenhormone einen direkten humoralen Angriffspunkt an jeder einzelnen Zelle haben Um welchen Wirkungsmechanismus es sich bei der Beeinflussung des Stoffwechsels handelt ist bis heute nicht geklärt Die Hormonwirkung lässt sich nach Lipner et al (1952) und Tabachnick et al. (1954) nicht an einen bestimmten Ort der Körperzelle festlegen Man hat jedoch den Eindruck als wenn den Mitochondrien in diesem Zusammenhang eine wesentliche Bedeutung zukommt Die gleichen Autoren weisen jedoch darauf hin dass das Thyroxin und das Trijodthyronin sich sehr unterschiedlich an verschiedenen Stellen der Zelle verhalten so im Kern in den Mitochondrien und Mikrosomen Unter dem Einfluss des Schilddrüsenhormons treten submikroskopische Veränderungen in Form von Mitochondrienquellungen unter Wasseraufnahme und Mitochondrienvermehrung in der Zelle auf Nach Hess und Brand (1964) werden dadurch intrazelluläre Enzymsysteme labilisiert und der Austausch im Stoffwechselmetabolismus zwischen den extra und intramitochondrialen Reaktionsräumen ermöglicht Diese Aussage stellt nur *einen* Aspekt zur Wirkweise der Schilddrüsenhormone dar ganz sicherlich werden noch mehrere Faktoren im Spiele sein

Man kann den Einfluss der Schilddrüsenhormone auf die Zellbestandteile in eine Sofort und eine Spätwirkung aufgliedern. Die Sofortwirkung bei der Anwendung niedriger Hormonkonzentrationen beruht auf einer Steigerung von ATP-Synthese und Sauerstoffverbrauch mit einer Stimulierung der Eiweisssynthese Bei der Spätwirkung nach höheren Hormondosen (etwa 12 Std nach Hormongabe) erfolgt eine Anregung der Glykolyse und Induktion von Enzymsynthesen (Hess und Brand 1964) Die Änderung oder besser der Anstoss zur Enzymneubildung wird durch

eine hormonbedingte Substratänderung hervorgerufen. Pitt-Rivers und Tata (1959) beschreiben die Aktivitätsänderung von etwa 50 Fermenten unter dem Einfluss des Schilddrüsenhormons.

Erhöhte Fermentaktivitäten nach Hormongaben zeigten sich erwartungsgemäss bei den am Elektronentransport beteiligten Enzymen über die Atmungskette, aber auch andere Fermente liessen erhöhte Fermentaktivitäten unter dem Einfluss von Schilddrüsenhormonen erkennen (Dye und Waggener 1928, Markoff, 1935, Barker 1951, Maley 1957, Rawson et al. 1955 u. a.). Mit grosser Wahrscheinlichkeit liegt keine spezifische Wirkung des Schilddrüsenhormones auf irgendein Ferment system vor. Die unterschiedlichen Fermentaktivitäten – Aktivitäts- ab- oder zunahme – beruhen mutmasslich auf der veränderten chemischen Zusammensetzung von Körperflüssigkeiten und in der variablen Dynamik des Stoffwechsels. Man kann – wie schon betont – also lediglich Enzymwirkungen darstellen, jedoch in diesem Zusammenhang keine Angaben über den Wirkungsmechanismus der Enzyme machen. Versucht man eine einfache Formulierung zur Hormonwirkung zu geben, so darf man festhalten, dass die Schilddrüsenhormone auf den Stoffwechsel an der Stelle der oxydativen Phosphorylierung einwirken und die Bereitstellung von energiereichen Phosphaten steuern (s. auch Oberdisse und Klein, 1967).

Die Schilddrüsenhormone beeinflussen alle Stoffwechselbereiche. Im Eiweisshaushalt wirken physiologische Hormonmengen anabol, sie stimulieren die Eiweissynthese und den Eiweissabbau. Grosse Hormonkonzentrationen wirken katabol, woraus ein Phosphatverlust und eine negative Stickstoffbilanz resultieren kann. Durch Hormonmangel kommt es neben der Grundumsatzerniedrigung zu Eiweissansammlung in Interzellulärräumen bei verminderter Proteinsynthese (Crispell et al. 1956, Lewallen et al. 1959). Bei zunehmendem Hormonmangel steigen die Gesamtproteine im Plasma an, während der Gehalt an Mukoproteinen im Plasma abnimmt (Mustacchi et al. 1954).

Der Kohlenhydrathaushalt wird durch verschiedene Fermente gesteuert, die unter dem *Einfluss von Schilddrüsenhormonen* stehen. Spezifische Wirkungen dieser Fermente bei physiologischem Hormonspiegel sind nicht bekannt. Im Fettstoffwechsel ist bei Hormonmangel seit langem die Hypercholesterinämie bekannt (Epstein und Lande, 1922). Auf weitere Einzelheiten kann in diesem Zusammenhang nicht eingegangen werden. Durch den Hormonmangel wird eine Wasser- und Elektrolytretention bei Dehydration von Blut, Muskulatur und Gehirn bewirkt. Scholz et al. (1964) stellten dabei fest, dass extra- und intrazelluläre Verteilungsräume gleichermassen beteiligt sind. Durch Hormonzufuhr *wird eine Diurese* ausgelöst, die zu einer Vermehrung des Blutvolumens auf Kosten der Extrazellularflüssigkeit führt (Pitt-Rivers und Tata, 1959).

Die Grundsubstanz des Bindegewebes steht in besonderem Masse unter dem Einfluss des Schilddrüsenhormons. Iversen (1954) applizierte Meerschweinchen Thyreotropin, was zu einer Vermehrung von hyaluronidasesensitiven sauren Mucopolysacchariden in verschiedenen Bindegewebsbereichen führte. Auffällig war die Unterschiedlichkeit der Reaktion in verschiedenen Bindegewebsarealen, z. B. wird das retrobulbäre Gewebe besonders betroffen (Asboe-Hansen und Iversen 1951, Iversen und Asboe-Hansen 1952). Mit grosser Wahrscheinlichkeit wird der Exophthalmus durch das hohe Wasserbindungsvermögen der Hyaluronsäure, welches eine oedematöse Aufquellung des Gewebes verursacht, hervorgerufen. Nach Ludwig et al. (1950) findet man in dem betroffenen Gewebe des retrobulbären Raumes eine erhebliche Steigerung der Metachromotropie. Das prätibiale Oedem des hypothyreotischen Patienten ist gekennzeichnet durch eine Vermehrung der Grundsubstanz, in der eine starke Zunahme von sauren Mukopolysacchariden beobachtet werden kann. Diese sauren MPS

sind partiell hyaluronidasesensitiv perjodat reaktiv metachromotrop und zeigen eine positive Eisenbindungsreaktion (Asboe Hansen *1950c* Palitz und Brunner 1950 Follis 1950 Brewer *1951* Campani und Pelloja 1951) Nach Gaben von Schilddrüsenhormonen nimmt der Gehalt an sauren Mukopoly sacchariden stark ab

Meyer und Chaffée (1941) Ludwig et al (1950) sowie Brewer (1951) führen das erhebliche Wasserbindungsvermögen im myxomatösen Gewebe auf den hohen Gehalt an Hyaluronsäuren zurück während sie die Chondroitin Schwefelsäure für die Alteration an den Bindegewebsfibrillen verantwortlich machen Das ausgeprägte Wasserbindungsvermögen des Mukopolysacchanid Proteinkomplexes beruht nach Bull (1951) auf der Anwesenheit von polaren Gruppen Bei längerem Bestehen des Myxoedems nimmt der Gehalt an Hyaluronsäure im Gewebe ab während die Chondroitin-Schwefelsäure zunimmt Darüberhinaus ist neben der quantitativen Veränderung der Mukopolysaccharide auch die Relation zwischen Hyaluronsäure und Chondroitinsulfatgehalt verschoben Während normalerweise im Bindegewebe auf 100 g Gewebe 25 mg Hyaluronsäure und 26 mg Chondroitin sulfat kommen findet sich beim lokalen Myxoedem ein Verhältnis von 64–270 mg Hyaluronsäure 49–160 mg Chondroitin-Sulfat Offensichtlich liegt das Phänomen darin begründet dass die freie Grundsubstanz welche normalerweise zu einem grossen Teil aus Hyaluronsäure besteht beim Myxoedem bevorzugt betroffen wird (Watson und Pearce 1947 1949 1950)

Del Conte et al (1955) hatten bei Ratten nach Thyreoidektomie und Anwendung thyreostatischer Substanzen eine Vermehrung von sauren MPS im Hautbindegewebe festgestellt Sie fanden jedoch keine direkte Beziehung zwischen der Vermehrung der sauren MPS und der Zahl der Mastzellen Asboe Hansen (1950*c*) jedoch hält nach seinen Untersuchungsergebnissen eine Beziehung zwischen den vermehrten sauren MPS und der Zahl der Mastzellen für sehr wahrscheinlich Die Mastzellen im Bindegewebe gehen beim Myxoedem starke Veränderungen ein. Sie weisen eine metachromatische Granulierung auf die sich unter dem Einfluss von Schilddrüsenhormonen zurückbildet Dieser Befund dürfte im Zusammenhang mit der Produktion saurer Mukopolysaccharide (Hyaluronsäure) durch die Mastzellen stehen eine Vorstellung, die besonders von Asboe Hansen (1950*a* *b* *c* 1954) propagiert wird Dafür spricht u a dass die Mastzellen und die Hyaluronsäure in den gleichen Bindegewebsprovinzen vorkommen um die Mastzellen sich häufig extrazellulär metachromotropes Material findet nach enzymatischem Abbau der Grundsubstanz eine Einwanderung von Mastzellen und deren Degranulierung beobachtet werden kann

Parallel zur Vermehrung der sauren Mukopolysaccharide im myxomatös veränderten Bindegewebe geht eine Erhöhung der Mukopolysaccharide im Serum (Mancini et al 1952)

Nicht alle Zusammenhänge zwischen Schilddrüsenhormonen und Bindegewebe sind bislang aufgeklärt worden Möglicherweise werden auch noch andere Mukopolysaccharide als die erwähnte Hyaluronsäure und das Chondroitinsulfat beteiligt worauf Brewer (1951) Farvilli (195?) sowie Keining und Braun-Falco (1956) hinwiesen

Asboe Hansen (1950*c*) nimmt an dass das Schilddrüsenhormon über seine stimulierende und hemmende Wirkung auf die thyreotrope Aktivitä der Hypophyse die Verteilung und Produktion der sauren MPS regelt d h die Vermehrung der sauren MPS beim Myxoedem als Folge der Überschussproduktion am thyreotropen Hormon zu erklären sind Angriffspunkt sollen nach Asboe Hansen die perivasculären Mastzellen sein

8 Einteilung der Hypothyreosen, klinische Symptomatik

Die Hypothyreosen *lassen sich in primäre* und *sekundäre Erkrankungen* einteilen. Im folgenden wird die Aufgliederung nach Scazziga und Lemarchand-Béraud (1966) zugrunde gelegt

I Primäre Hypothyreose

a) Hypothyreose infolge quantitativ gestörter Hormonbildung

  aa) Hypothyreose infolge Fehlens oder Verminderung des funktionierenden Schilddrüsengewebes

  bb) Idiopathische Hypothyreose des Kindes und des Erwachsenen

b) Hypothyreose infolge qualitativer Störung der Hormonsynthese

  aa) Erworbene Störungen der Hormonsynthese aus exogenen oder endogenen Gründen

  bb) Kongenitale Störung der Hormonsynthese

II Sekundäre Hypothyreose

a) Sekundäre Hypothyreose bei Läsionen im ZNS

b) Sekundäre Hypothyreosen infolge Jodmangels

Aus der Vielzahl der Ursachen für eine verminderte oder aufgehobene Funktion der Schilddrüse soll die primäre Hypothyreose herausgegriffen werden, da sie am ehesten den durchgeführten experimentellen Untersuchungen entspricht. Noch weiter einschränkend wird besonders die Form der Hypothyreose besprochen, die im Erwachsenenalter auftritt und auf einer quantitativen Störung der Hormonproduktion beruht. *Sie kann durch mangelhaft angelegtes* Schilddrüsengewebe entstehen oder aber Folge einer zu radikalen Strumektomie sein. Zum anderen lässt sie sich auf eine *Thyreoiditis (z. B. Hashimotothyreoiditis)* oder einen malignen Schilddrüsentumor zurückführen.

Die Hypothyreose kommt in verschiedenen Stärkegraden vor, was sich klinisch in einer manchmal nur diskreten Symptomatik, in anderen Fällen im voll ausgeprägten Krankheitsbild des Myxoedems äussert. Der Grad der mangelhaften Hormonproduktion lässt sich durch die Bestimmung des proteingebundenen Serumjods festhalten, wobei Werte zu *meist unter 4,5 µg/100 ml vorliegen. Weitere* diagnostische Massnahmen wie Messung des Radiojodumsatzes, Stimulierung der Schilddrüse mit thyreotropem Hormon und Szintigraphie sollen nur am Rande erwähnt werden.

Bei starker *Unterfunktion der Schilddrüse* liegt häufig ein Myxoedem der Haut mit Prädilektionsstellen im prätibialen Bereich des Unterschenkels vor. Die Patienten zeigen eine abnorme Ermüdbarkeit und Apathie, es stellen sich Störungen der Merkfähigkeit, der Konzentration und des Antriebes ein. *Sehr* typisch ist eine hartnäckige Obstipation. Bei der nur leichten *Form der Schilddrüsenunterfunktion* kann die *Diagnostik* Schwierigkeiten bereiten, da sich *typische Symptome nur diskret* äussern und häufig genug Anlass zu *Fehlinterpretationen des Krankheitsbildes er*geben. Weitere *Einzelheiten der Symptomatik* und *Diagnostik der Schilddrüsenunterfunktion* lassen sich den ausführlichen Darstellungen von *Oberdisse und Klein (1967), König (1968), Klein (1969) u. a.* entnehmen.

sind partiell hyaluronidasesensitiv perjodatreaktiv metachromotrop und zeigen eine positive Eisenbindungsreaktion (Asboe-Hansen 1950*c* Palitz und Brunner 1950 Follis 1950 Brewer 1951 Campani und Pelloja 1951) Nach Gaben von Schilddrüsenhormonen nimmt der Gehalt an sauren Mukopolysacchariden stark ab

Meyer und Chaffée (1941) Ludwig et al (1950) sowie Brewer (1951) führen das erhebliche Wasserbindungsvermögen im myxomatösen Gewebe auf den hohen Gehalt an Hyaluronsäuren zurück während sie die Chondroitin-Schwefelsäure für die Alteration an den Bindegewebsfibrillen verantwortlich machen Das ausgeprägte Wasserbindungsvermögen des Mukopolysaccharid Proteinkomplexes beruht nach Bull (1951) auf der Anwesenheit von polaren Gruppen Bei längerem Bestehen des Myxoedems nimmt der Gehalt an Hyaluronsäure im Gewebe ab während die Chondroitin Schwefelsäure zunimmt Darüberhinaus ist neben der quantitativen Veränderung der Mukopolysaccharide auch die Relation zwischen Hyaluronsäure und Chondroitinsulfatgehalt verschoben Während normalerweise im Bindegewebe auf 100 g Gewebe 25 mg Hyaluronsäure und 26 mg Chondroitinsulfat kommen findet sich beim lokalen Myxoedem ein Verhältnis von 64–270 mg Hyaluronsäure : 49–160 mg Chondroitin-Sulfat Offensichtlich liegt das Phänomen darin begründet dass die freie Grundsubstanz welche normalerweise zu einem grossen Teil aus Hyaluronsäure besteht beim Myxoedem bevorzugt betroffen wird (Watson und Pearce 1947 1949 1950)

10 Besprechung der Ergebnisse

Gehörstörungen als Begleitsymptom von Schilddrüsenfunktionen im Sinne einer Hypothyreose kommen überwiegend bei drei Erkrankungen vor die kurz noch einmal angeführt werden sollen

1. Der endemische Kretinismus
2. Das sog. Pendred-Syndrom.
3. Die primäre Hypothyreose infolge quantitativ und qualitativ gestörter Hormonbildung

Die beiden ersten Formen der endemische Kretinismus und das sog. Pendred-Syndrom in Verbindung mit Hörstörungen können hinsichtlich der Genese der Innenohrstörung nur Gegenstand von Denkmodellen sein da es wohl kaum oder nur sehr schwer gelingen wird entsprechende experimentelle Untersuchungen anzustellen Die von früheren Autoren aufgezeigten pathologisch-anatomischen Substrate des Innenohres beim endemischen Kretin deuten in ihrer Gesamtheit am ehesten auf Missbildungen hin andererseits kann man sich des Eindruckes nicht erwehren dass manche der beschriebenen Veränderungen insbesondere die im Innenohr gelegenen, post mortal entstanden und Folge fortschreitender Autolyse sind ein Einwurf der auch von früheren Autoren gemacht wurde. Gerade die morphologischen Innenohrbestandteile sind in einem besonderen Ausmass gegen post mortale Veränderungen empfindlich Nicht selten kann man beim Tierkada er (Meerschweinchen) schon nach 24-48 Std kein Cortiorgan mehr nachweisen

Die Ergebnisse der pathologisch-anatomischen Untersuchungen müssen auch schon deswegen enttäuschen als sie in den meisten Fällen die schwere Schallempfindungsstörung nicht erklären können Zum anderen muss man die technischen Möglichkeiten zur Schnittherstellung mit langdauernden Entkalkungsprozessen in Rechnung stellen, wodurch das morphologische Substrat in einem Ausmasse altenert wird welches Rückschlüsse auf eine mögliche Funktionsbeeinträchtigung, basierend auf einer Schädigung des Schallperzeptionsapparates, gar nicht mehr zulässt. Ein letztes wichtiges Argument gegen die Aussagekraft der erhobenen Befunde ist die Tatsache dass endemischer Kretinismus und schwere Hörstörungen bzw Taubstummheit nebeneinander ohne direkten Zusammenhang vorkommen können – wie es besonders von Schweizer Autoren betont wurde – dass also im vorliegenden Falle patho-morphologische Veränderungen im Innenohr der Schilddrüsendysfunktion zugeordnet werden, deren Verantwortlichkeit für die erhobenen Befunde zumindest in Zweifel gezogen werden kann.

Experimentelle Untersuchungen über die Beeinflussung des Innenohres durch die Hypothyreose lassen sich nur durch Verminderung oder totale Entfernung von Schilddrüsengewebe anstellen sei es durch operative Entfernung der Schilddrüse, wie in den vorliegenden Experimenten ausgeführt oder aber durch Blockierung des Jodeinbaus zu Monojodtyrosin mittels Thiouracil (Ritter und Lawrence 1960; de Vos 1963 Ritter 1967) Das Versuchsmodell würde danach vergleichbar sein mit der primären Hypothyreose infolge Mangel an Schilddrüsenhormonen eine Erkrankung, die elektroakustisch nachweisbare Hörverluste häufig über das ganze Tonfrequenzband hin erzeugt.

Die mikromorphologische Untersuchung des Innenohres beim Meerschweinchen unter Mangel an Schilddrüsenhormonen gestaltet sich insofern überaus schwierig als die zu erwartenden und auch überraschenden Ergebnisse in ihrer Deutung auf die komplexe Wirkungsweise der Hormone abgestimmt werden müssen d. h. die vielfältigen Angriffspunkte des Thyroxins werden eine Vielzahl von Veränderungen in den einzelnen Innenohrstrukt-

9 Experimentelle Arbeiten zum Einfluss der Schilddrüsenhormone auf das Gehororgan (aus der Literatur)

Nach Durchsicht der otologischen Literatur liegen nur wenige experimentelle Arbeiten zur Entstehungsursache der hypothyreotisch bedingten Schwerhörigkeit vor So finden sich Arbeiten von Poulsen (1959) Ritter und Lawrence (1960) de Vos (1963) sowie Ritter (1967)

Poulsen (1959) untersuchte die Innenohrstrukturen von thyreoidektomierten Meerschweinchen mit histologisch histochemischen Methoden und stellte dabei vermehrte Ansammlungen von Hyaluronsäure im Endo- und Perilymphraum fest Zum anderen beobachtete er eine Vermehrung von Mastzellen in den entsprechenden Strukturen. Der Autor diskutiert aufgrund seiner Beobachtungen und Untersuchungsbefunde die Möglichkeiten der Entstehung einer Schwerhörigkeit im Ablauf einer Hypothyreose

Ritter (1967) verwendete für seine Untersuchungen Hühnchenembryonen denen er am 4 9 und 14 Tag nach Beginn der Bebrütung 2 mg Thiouracil injizierte Nach Ausschlüpfen der Tiere die sofort getötet wurden zeigten sich bei den Hühnchen die am 9 und 14 Tag Thiouracil erhielten keine auffälligen Veränderungen im Bereich der akustischen Papille Erst die am 4 Tag nach Beginn der Bebrütung injizierten Tiere liessen nach Ansicht des Autors Alterationen erkennen die auf Mangel an funktionierendem Schilddrüsengewebe zurückgeführt wurden Die Tiere schlüpften etwas verspätet aus dem Ei hatten unterentwickelte Flügel der Dottersack war unvollständig resorbiert Die Hauptveränderungen lagen im Bereich des Innenohres (akustische Papille) während im Mittelohr lediglich eine Verknöcherungsstörung des Steigbügels nachweisbar war Im Innenohr zeigte die Tectorialmembran einen Kontakt mit den Haarzellen diese jedoch waren zahnförmig deformiert und von den Nervenfasern durch ein deutliches Oedem im Zwischengewebe getrennt Die angeführten Veränderungen fanden sich bei allen untersuchten Hühnchen die während der Inkubation am 4 Tag 2 mg Thiouracil erhalten hatten

De Vos (1963) verabreichte weissen Mäusen weissen Ratten und Hamstern Propyl thio-Uracil (5%ige wässerige Lösung) über 6–21 Wochen Danach wurden die Tiere getötet und die Felsenbeine nach Fixierung und Entkalkung in Celloidin und Paraffin eingebettet und mit Hämatoxilin Eosin gefärbt Die morphologische Alteration des Innenohres, welche sich nach Ansicht des Autors nach 7 wöchiger Thiouracilbehandlung einstellte wurde als leichte bis mittelschwere Degeneration der Spiralganglien beschrieben Leichte degenerative Zeichen bemerkte de Vos auch am N acusticus. Darüberhinaus beobachtete er eine Verdickung der Basilarmembran Der Autor betont die Verschiedenartigkeit zwischen den Gehörstörungen beim Kretinismus beim Pendred Syndrom und bei der Schwerhörigkeit infolge einer im späteren Lebensalter erworbenen Hypothyreose Er stimmt der Hypothese von Trotter (1960) zu dass möglicherweise der Schilddrüsenmangel keine entscheidende Rolle für die Hörstörung spielt sondern eine schädliche im Blut zirkulierende Substanz die Enzymstörungen im Hörorgan und in den zentralen Schaltstellen verursacht dafür verantwortlich ist

Schliesslich begannen Schätzle und Haubrich (1967) eine differenzierte histomorphologische Bearbeitung der Innenohrstrukturen bei der experimentellen Hypothyreose des Meerschweinchens

wechsel der äusseren Haarzellen fest erst später machten sich Veränderungen an den inneren Haarzellen bemerkbar Die verschiedenartige Empfindlichkeit der äusseren und inneren Haarzellen kann als Beweis für die Duplizitätstheorie des Hörens herangezogen werden die von Meyer zum Gottesberge (1948) formuliert wurde. Danach kommt den verschiedenen Sinneszellen im Cortiorgan eine unterschiedliche Funktion hinsichtlich der Hörschwelle und der Frequenzanalyse zu

Berücksichtigt man zunächst die experimentellen Ergebnisse zur quantitativen und qualitativen Verteilung der Fermente in den Innenohrstrukturen unter Mangel an Schilddrüsenhormonen so darf man vorausschicken dass die Änderung der Enzymaktivität an den einzelnen Orten des Innenohres relativ diskret ist, sich aber bei genauer mikroskopischer Exploration der histochemischen Schnitte deutlich abzeichnet Insbesondere fällt die Abnahme der Enzymaktivität bei der Esterase- und Glukosaminidasereaktion auf In Übereinstimmung mit anderen Autoren dokumentiert sich die quantitative Änderung des Fermentgehaltes überwiegend in den äusseren Haarzellen und nicht zuletzt in der Stria vascularis und im Ganglion spirale Bei manchen Glykosidasen (Galaktosidase und Glukuronidase) kann keine eindrucksvolle Änderung der Enzymkonzentration dokumentiert werden, während die N Azetyl-Glukosaminidase in den äusseren Haarzellen in der Stria vascularis und im Ganglion spirale erheblich abnimmt. Die Sulfatase-Reaktion ist unverändert kräftig. Eine ähnliche Situation liegt auch im Saccus endolymphaticus vor dessen aktive Zone der Pars intermedia eine sehr auffällige Reduzierung von Enzymaktivitäten der unspezifischen Esterase und der Glukosaminidase erkennen lässt

Zur Deutung der angeführten Fermentbefunde lassen sich verschiedene Gesichtspunkte anführen deren Wertigkeit im einzelnen nur abgeschätzt, im Gesamtbild jedoch recht einheitlich beurteilt werden kann

Wie Hess und Brand (1964) formulierten kommt es durch Zufuhr von Schilddrüsenhormonen zu einer intrazellulären Labilisierung von Multienzymsystemen mit vermehrtem extra- und intrazellulären Stoffaustausch Durch Substratänderung infolge einer Hypo- oder Hyperthyreose wird eine Induktion von verschiedenen Fermenten bedingt die sich im Ansteigen oder Abfallen von Enzymaktivitäten äussern kann. Als Beispiel mag das Verhalten der Galaktosidase der Glukuronidase und der Sulfatase dienen Alle diese Fermente spielen mit einer hohen Wahrscheinlichkeit eine wichtige Rolle im Stoffwechsel der Gluko-Mukoproteide und sauren Mukosubstanzen deren Abbau sie an bestimmten Bindungen vollziehen. Es kann keinen Zweifel darüber geben dass infolge der Hypothyreose durch vermehrte histochemisch manchmal nicht zu erfassende Ablagerungen von Mukosubstanzen eine Adaptation der Fermentaktivität an das veränderte Substrat z.B der Bindegewebsgrundsubstanz vonstatten geht die sich in einer Aufrechterhaltung eines bestimmten Enzymstatus oder sogar Vermehrung äussern kann In besonderem Masse scheint der Aryl-Sulfatase eine Bedeutung für den cochlearen Stoffwechsel sulfatierter Glukoproteide und Mukopolysaccharide zuzukommen So findet sich auch dieses Ferment bei der Hypothyreose in einer starken Aktivität. Auffällig bleibt jedoch die Abnahme der N-Azetyl-Glukosaminidase deren grosse Bedeutung für die Aufschlüsselung der sauren Mukopolysaccharide mit deren Hauptbestandteil N Azetyl-Glukosamin bekannt ist.

Von gleichem Interesse erscheint auch die hohe Enzymaktivität der Sulfatase an Orten des Innenohres die eine Bedeutung für die Sekretion und Resorption der Peri- und Endolymphe haben wie die Stria vascularis Sulcus spiralis externus Plexus cochlearis mit dem Tractus spiralis arteriosus et venosus, Saccus endolymphaticus u. a. Vergleiche von Enzymkonzentrationen an verschiedenen Bereichen der Cochlea und des Saccus endolymphaticus mit den autoradiographisch gemessenen Eiweissumsätzen an den entspre

turen bedingen deren morphologische Darstellbarkeit auf Schwierigkeiten stossen kann.

Der ungestörte oxydative Stoffwechsel ist eine Hauptvoraussetzung für eine normale Haarzellfunktion was von Misrahy et al (1958) besonders hervorgehoben wurde Tritt ein Mangel an Sauerstoff ein werden sich die Haarzellen auf Grund ihres hohen Gehaltes an Lactatdehydrogenase (Vosteen 1961 1964) über die anaerobe Glykolyse für eine kurze Zeit einen ausreichenden Zellstoffwechsel sichern Der Stria vascularis hingegen fehlt weitgehend diese Fermentausstattung so dass sie schon recht frühzeitig unter einer Hypoxydose geschädigt wird Neben der LDH wies Vosteen auch Glutamatdehydrogenase und Alpha-Glyzero-Phosphatdehydrogenase nach deren Verbreitung im Innenohr weitgehend der der LDH entspricht Im Gegensatz zu diesen Ergebnissen fanden Spoendlin und Balogh (1963*a* *b*) die LDH fast ausschliesslich in den äusseren Haarzellen und hier in schwankender Aktivität Bei der Hypothyreose kann als ziemlich sicher gelten dass die oxydative Phosphorylierung in ihrem Fermentspektrum als Angriffspunkt des Schilddrüsenhormons gestört und die Reservestellung von energiereichen Phosphaten vermindert wird Da die Haarzellen insgesamt bei einer Reduzierung oxydativer Stoffwechselvorgänge sehr empfindlich reagieren liesse sich dadurch die oftmals zu beobachtende Beeinträchtigung aller Tonfrequenzen d h die Funktionsherabsetzung aller Haarzellen erklären Die Haarzellen der Basalwindung sind ohnehin aufgrund ihrer höheren Belastung empfindlicher als die Hörzellen der anderen Windungen was sich im Audiogramm durch einen stärkeren Hörverlust im Hochtonbereich dokumentieren wird Mutmasslich dürfte der Grad der hypothyreotischen Stoffwechsellage einen Einfluss auf die Funktionsbeeinträchtigung der Haarzellen haben was aber von manchen Autoren bestritten wird (de Vos 1963 Post 1964) Diese Autoren fanden Patienten mit relativ leichter Hypothyreose und stärkerer Hörstörung andere Kranke litten an einem voll ausgeprägten Myxoedem ohne dass eine Schwerhörigkeit nachweisbar war Dieser Befund erscheint insofern bemerkenswert als die Herabsetzung der oxydativen Phosphorylierung infolge Mangels an Schilddrüsenhormonen in ihrer graduellen Abstufung kein alleiniges Kriterium für das Ausmass der Innenohrstörung sein kann Man muss von der Überlegung ausgehen dass die Ursache der Innenohrstörung rein anatomisch gesehen an verschiedenen Stellen der Cochlea lokalisiert sein kann 1 an den Haarzellen 2 am N acusticus mit seinen präganglionären und postganglionären Fasern und 3 am sezernierenden und resorbierenden System des gesamten Ductus cochlearis (z B Stria vascularis Limbus spiralis Prominentia spiralis u a) und des Ductus sowie Saccus endolymphaticus Daraus liessen sich Schlüsse über mögliche Störungen der Elektrolytverhältnisse in Endo- und Perilymphe ableiten

Am leichtesten lassen sich die hin und wieder relativ selten auftretenden Schalleitungsstörungen beim Myxoedem erklären da hier durch eine erhebliche Schwellung der Mittelohrschleimhaut und eine sich daraus ergebende gewisse Versteifung der Gehörknöchelchen eine Schwingungsbeeinträchtigung des schallübertragenden Apparates verursacht wird Diesen Befund konnten wir an einigen Tieren beobachten

Die äusseren und inneren Haarzellen besitzen aufgrund histologischer histochemischer und elektrophysiologischer Untersuchungen eine sehr unterschiedliche Anfälligkeit gegenüber schädlichen Einwirkungen Rüedi (1951) beobachtete bei Streptomycingaben und Beschallung in Tierversuchen zunächst eine Schädigung der äusseren Haarzellen erst später traten Läsionen der inneren Haarzellen hinzu Vosteen (1958) wies nach funktioneller Belastung zunächst eine Fermentabnahme in den äusseren Haarzellen nach Beck (1959) stellte bei Reintonbeschallung reversible Zellkernveränderungen und eine Störung im Eiweiss und RNS Stoff

wechsel der äusseren Haarzellen fest erst später machten sich Veränderungen an den inneren Haarzellen bemerkbar Die verschiedenartige Empfindlichkeit der äusseren und inneren Haarzellen kann als Beweis für die Duplizitätstheorie des Hörens herangezogen werden, die von Meyer zum Gottesberge (1948) formuliert wurde. Danach kommt den verschiedenen Sinneszellen im Cortiorgan eine unterschiedliche Funktion hinsichtlich der Hörschwelle und der Frequenzanalyse zu

Berücksichtigt man zunächst die experimentellen Ergebnisse zur quantitativen und qualitativen Verteilung der Fermente in den Innenohrstrukturen unter Mangel an Schilddrüsenhormonen so darf man vorausschicken dass die Änderung der Enzymaktivität an den einzelnen Orten des Innenohres relativ diskret ist, sich aber bei genauer mikroskopischer Exploration der histochemischen Schnitte deutlich abzeichnet Insbesondere fällt die Abnahme der Enzymaktivität bei der Esterase und Glukosaminidasereaktion auf In Übereinstimmung mit anderen Autoren dokumentiert sich die quantitative Änderung des Fermentgehaltes überwiegend in den äusseren Haarzellen und nicht zuletzt in der Stria vascularis und im Ganglion spirale Bei manchen Glykosidasen (Galaktosidase und Glukuronidase) kann keine eindrucksvolle Änderung der Enzymkonzentration dokumentiert werden, während die N Azetyl-Glukosaminidase in den äusseren Haarzellen in der Stria vascularis und im Ganglion spirale erheblich abnimmt. Eine ähnliche Situation liegt auch im Saccus endolymphaticus vor dessen aktive Zone der Pars intermedia eine sehr auffällige Reduzierung von Enzymaktivitäten der unspezifischen Esterase und der Glukosaminidase erkennen lässt

Zur Deutung der angeführten Fermentbefunde lassen sich verschiedene Gesichtspunkte anführen deren Wertigkeit im einzelnen nur abgeschätzt, im Gesamtbild jedoch recht einheitlich beurteilt werden kann.

Wie Hess und Brand (1965) *formulierten*, kommt es durch Zufuhr von Schilddrüsenhormonen zu einer intrazellulären Labilisierung von Multienzymsystemen mit vermehrtem extra und intrazellulären *Stoffaustausch*. Durch Substratänderung infolge einer Hypo- oder Hyperthyreose wird eine Induktion von verschiedenen Fermenten bedingt die sich im Ansteigen oder Abfallen von Enzymaktivitäten äussern kann. Als Beispiel mag das Verhalten der Galaktosidase der Glukuronidase und der Sulfatase dienen Alle diese Fermente spielen mit einer hohen Wahrscheinlichkeit eine wichtige Rolle im Stoffwechsel der Gluko-Mukoproteide und sauren Mukosubstanzen deren Abbau sie an bestimmten Bindungen vollziehen Es kann keinen Zweifel darüber geben dass infolge der Hypothyreose durch vermehrte histochemisch manchmal nicht zu erfassende Ablagerungen von Mukosubstanzen eine Adaptation der Fermentaktivität an das veränderte Substrat z. B der Bindegewebsgrundsubstanz vonstatten geht die sich in einer Aufrechterhaltung eines bestimmten Enzymstatus oder sogar Vermehrung aus sern kann. In besonderem Masse scheint der Aryl Sulfatase eine Bedeutung für den cochleären Stoffwechsel *sulfatierter Glukoproteide* und Mukopolysaccharide zuzukommen So findet sich auch dieses Ferment bei der Hypothyreose in einer starken Aktivität. Auffällig bleibt jedoch die Abnahme der N Azetyl *Glukosaminidase* deren grosse Bedeutung für die Aufschlüsselung der *sauren Mukopolysaccharide* mit deren Hauptbestandteil N Azetyl-Glukosamin bekannt ist.

Von gleichem Interesse erscheint auch die hohe Enzymaktivität der Sulfatase an Orten des Innenohres, die eine Bedeutung für die Sekretion und Resorption der Peri- und Endolymphe haben wie die Stria vascularis Sulcus spiralis *externus Plexus cochlearis* mit dem Tractus spiralis arteriosus et venosus Saccus endolymphaticus u a. Vergleiche von Enzymkonzentrationen an verschiedenen Bereichen der Cochlea und des Saccus endo*lymphaticus* mit den autoradiographisch gemessenen Eiweissumsätzen an den entspre

chenden Strukturanteilen zeigen deutlich eine Übereinstimmung von Fermentaktivität und Höhe des Eiweissumsatzes (Plester 1960 Meyer zum Gottesberge und Plester 1961 Koburg und Plester 1962*a* *b* Balogh und Koburg 1965) Die Inkorporationsraten von H_3 Leucin H_3-Tyrosin und H_3-Phenyl Ala nin ergaben beträchtliche Werte für die Stria vascularis was sich in der chromophilen endolymphnahen und weniger in der chromophoben Schicht abzeichnete (Koburg und Plester 1962*a*)

Entsprechende Befunde zeigten sich am Saccus endolymphaticus dessen hoher Gehalt an Sulfatase im gesamten Epithelbereich und vorzugsweise in der Pars intermedia von Schätzle und Haubrich (1966) und hoher Eiweissumsatz mit H_3 Phenyl Alanin autoradiographisch von Haubrich und Koburg (1966) sowie Koburg et al (1967) nachgewiesen wurde

Als Parallelbefund mag der hohe Gehalt der Stria vascularis an sog freien Sulfhydrylen dienen die von Rauch (1964) als möglicher Beweis für die Anwesenheit SH abhängiger Fermente (Carboanhydrase Esterase) angeführt wurden Auch unter hypothyreotischen Bedingungen nimmt der Gehalt von Sulfhydrylen nicht ab

Infolge der Schilddrüsenunterfunktion erwartet man eine verminderte Proteinsynthese mit vermehrter Eiweissansammlung im Interzellularraum (Crispell et al 1957 Rothschild et al 1957 Lewallen et al 1959) Soweit man die Befunde am Innenohr des Meerschweinchens deuten kann darf man vielleicht annehmen dass eine ausreichende Proteinsynthese zumindest für die infolge Substratänderungen induzierten Fermente trotz Schilddrüsenunterfunktion gewährleistet wird

Dass PAS positive eosinophile nicht saure und nicht hyaluronidasesensible Material welches sich bei einigen Tieren im Bereich des Modiolus nachweisen lässt kann als extrazellulär gelagertes Glukoproteid (=Fibrinoid) gedeutet werden Ob für die Auswanderung der grossmolekularen Peptide und Proteine eine durch die Hypothyreose bedingte hypoxische Wandschädigung der Gefässe verantwortlich gemacht werden kann soll nur am Rande diskutiert werden

Eine weitere Struktur des Innenohres, der N acusticus ist gleichfalls von einer ungestörten Proteinsynthese abhängig. Weiss und Hiscoe (1948) stellten die Theorie des axonalen Stofftransportes von der Ganglienzelle in das zugehörige Axon auf Man hat sich darunter eine Zytoplasmawanderung aus dem Perikaryon der Ganglienzelle in das Axon vorzustellen Diese Untersuchungen wurden im einzelnen von Koenig (1958) Friede (1959) Droz und Leblond (1963) Lux et al (1970*a* *b*) am peripheren und zentralen Nerven histochemisch und autoradiographisch durchgeführt Haubrich und Koburg (1967) stellten eine beträchtliche Eiweissmigration im N acusticus nach zentral und peripher mit Hilfe der Messung von Inkorporationsraten bestimmter tritiummarkierter Aminosäuren (H_3-Tyrosin H_3-Phenyl Alanin H_3-Leucin) in verschiedenen Zeitabständen nach der Injektion fest Ohne Zweifel ist eine intakte Reizleitung im Nerven vom ungestörten Flow von Zytoplasmaanteilen aus der Ganglienzelle in das Axon abhängig Im folgenden wird noch ersichtlich werden inwiefern die Voraussetzung des intakten „axonal flow aufgrund der hypothyreotischen Stoffwechsellage durchbrochen und hiermit ein Aspekt zur Aufklärung der resultierenden Innenohrstörung dargelegt werden kann Damit zusammenhängend kommt auch der Abnahme der N Azetyl-Glukosaminidase in den Spiralganglienzellen bei der Hypothyreose als Ausdruck der verminderten Proteinsynthese eine Bedeutung zu Das im Stoffwechsel der Muko- und Glukosubstanzen eine dominierende Rolle spielende Ferment wird normalerweise in hoher Konzentration in den Ganglienzellen angetroffen

Die von de Vos (1963) erhobenen Befunde bei hypothyreotischen Nagern in Form von degenerativen Veränderungen an den Zellen des Ganglion spirale liessen sich durch die

histochemischen Befunde nicht verifizieren. Da jedoch die Schnitte von de Vos überwiegend nur mit Hämatoxylin-Eosin gefärbt wurden, muss man das Ergebnis mit Zurückhaltung beurteilen, zumal die sog. degenerativen Veränderungen eine weite Palette pathomorphologischen Substrats mit einer gewissen Unverbindlichkeit in der Aussagekraft umspannen.

Ein weiteres sehr eindrucksvolles Ergebnis zeichnet sich bei der Darstellung der Gluko-Mukoproteide und sauren Mukosubstanzen beim hypothyreotischen Meerschweinchen ab. Wie im experimentellen Teil der Arbeit ausführlich dargestellt, findet sich in den verschiedenen Skalen und in der Umgebung des *N.* acusticus sowie des Plexus cochlearis teilweise perjodatreaktives, teilweise hyaluronidasesensitives metachromotropes Material, welches bei Kontrolltieren nicht beobachtet werden kann. Auch im Saccus endolymphaticus fällt eine alcianophile hyaluronidaseempfindliche Substanz auf, während normalerweise dort ein nur PAS-positives Material aufgefunden wird (Mukoproteide). Beim Kontrolltier sind im Gegensatz zu den hypothyreotischen Tieren die Skalen optisch leer, was jedoch kein Beweis für die Anwesenheit oder Abwesenheit von sauren Mukosubstanzen in den Innenohrflüssigkeiten darstellt. Die Nichtfärbbarkeit der Endo- und Perilymphe ergibt lediglich einen Hinweis für nur sehr geringe Mengen der beschriebenen Substanzen.

Um die Bedeutung der sauren Mukopolysaccharide für den Hörvorgang zu verstehen, muss kurz auf wesentliche Arbeiten zu diesem Thema zurückgegriffen werden. Békésy nahm eine biologische Stromquelle in der Scala media an, die die hohe Potentialdifferenz zwischen der positiven Endolymphe und dem negativen Potential der Haarzellen aufrecht erhält. Biochemisch konnten Vilstrup und Jensen (1954) hyaluronidasesensible saure MPS in der Endolymphe von Selachiern ausmachen, was hingegen in der Perilymphe nicht gelang. Jensen, Koefoe und Vilstrup (1954) machten Modellversuche, indem sie eine Kaliumhyaluronatlösung in einem Glasrohr mit folgendem Ergebnis bewegten. Wurde die hyaluronhaltige Flüssigkeit in Bewegung gesetzt, so entstand in der Bewegungsrichtung ein positives, am anderen Ende der Flüssigkeitssäule ein negatives Potential (Displacements potentials). Diese Verschiebepotentiale wurden von Christiansen, Jensen und Vilstrup (1961) sowie Christiansen (1962) als Biegungspotentiale fadenartiger Polyelektrolyte gedeutet. Dohlmann (1960) bezieht gleichfalls die Mukopolysaccharide als wichtiges Substrat für die Schalltransformation im Bereich der Cochlea mit ein. Der Autor stellte fest, dass die grössten Potentialänderungen in der unmittelbaren Umgebung der Sinneshaare zu finden waren. Durch eine Absorbierung von Hyaluronatmolekülen an den Haaren wird bei der Verschiebung derselben infolge eines adäquaten Reizes in Gegenwart der Kaliumionen in der Endolymphe ein Verschiebepotential ausgelöst. Dabei ist zu beachten, dass die durch die Sinneshaare bewirkte erhebliche Oberflächenvergrösserung der Haarzelle eine Zellmembran darstellt, die nicht für Elektrolyte durchgängig ist. Sie bildet nach Dohlmann eine dielektrische Schicht, so dass ihr bei der grossen endolymphwärts gerichteten Fläche eine Kondensatorwirkung zukommt.

Citron und Exley (1957) fanden bei Meerschweinchen in der Peri- und Endolymphe Hexosamin in geringen Mengen (5–8 mg%). Schmieder und Schindler (1968) wiesen biochemisch N-Azetyl-Glukosamin in *niedriger* Konzentration in der Peri- und Endolymphe nach. Ishiyama (1969) konnte durch Dünnschichtchromatographie geringe Mengen von sauren Mukosubstanzen in den Innenohrflüssigkeiten isolieren (weniger als 3 mg/100 ml).

Letztlich sei noch auf die Ionenverhältnisse in der Endo- und Perilymphe hingewiesen. Die Endolymphe stellt in ihrer Zusammensetzung eine kaliumreiche extrazelluläre Flüssigkeit dar, während die Perilymphe eine hohe Konzentration von Natrium aufweist (Davis et al. 1958, 1959; Rauch, 1964 u. a.). Die

Bedeutung der Elektrolyte für die Hörfunktion muss sehr hoch eingeschätzt werden da die hydrostatischen und energetischen Funktionen in direktem Zusammenhang mit der normalen Elektrolytverteilung in der Innenohrflüssigkeit stehen

Donnan (1911) konnte zeigen dass sich frei diffundierende Elektrolyte zweier durch eine Membran getrennter Flüssigkeiten ungleich verteilen wenn auf der einen Seite nicht diffusible Elektrolyte vorliegen d h wenn auf der einen Seite nicht diffusible Stoffe mit hoher Ionenbindungskraft wie z B Mukopolysaccharide vorhanden sind Aus diesen Gesetzmässigkeiten würde sich ableiten lassen dass im vorliegenden Fall auf der Seite der negativ geladenen Polyelektrolyte (MPS) die Konzentration diffusibler Elektrolyte am höchsten ist.

Nun hat die Membrana tectoria einen hohen Gehalt an sauren Mukopolysacchariden worauf Belanger (1953) Dohlmann (1960) Dohlmann et al (1959) *Dohlmann und Ormerod* (1960) aufgrund ihrer autoradiographischen Arbeiten hinwiesen Über die Polyelektrolytwirkung der Mukopolysaccharide der *Membrana tectoria* berichteten wie schon erwähnt Vilstrup und Jensen (1954) Jensen Koefoe und Vilstrup (1954) Die Mukopolysaccharide wirken sich also im Donnan *Gleichgewicht in der Beziehung zwischen Peri-* und Endolymphe aus Nach alledem kann diskutiert werden ob nicht ein passiver Wasser und Ionentransport von der Perilymphe über *die Endolymphe zum Gefässystem möglich* ist (s auch Rauch 1964)

In diesem Zusammenhang gewinnen die experimentell erhobenen Befunde zur Verteilung der Mukopolysaccharide in den Innenohrstrukturen bei der Hypothyreose erhebliches Interesse Durch die Anhäufung von histochemisch nachweisbaren sauren Mukopolysacchariden in den verschiedenen Skalen der Cochlea insbesondere im Bereich der Scala vestibuli und tympani wird nach den Gesetzmässigkeiten des Donnan-Gleichgewichts eine Diffusion von Kaliumionen von der Endolymphe zu den anionischen Polyelektrolyten der Perilymphe stattfinden also eine gege[n]sätzliche Richtung des vermuteten Flüssi[g]keitsstromes von der Perilymphe in die End[o]lymphe Infolge dieser Kaliumverschiebu[ng] wird das für den normalen Hörvorgang wic[h]tige Kaliumionen Natriumionen-Verhältn[is] in Endo- und Perilymphe verschoben Au[s]serdem kann es durch zusätzliche Ablag[e]rungen von sauren MPS in der Scala med[ia] zu einer *Vermehrung von negativen Polyelek*trolyten kommen denn man muss berück*sichtigen dass die Membrana tectoria eben*falls einen hohen Gehalt an sulfatierten Mu*kopolysacchariden aufweist*

Die vermehrte Ansammlung von Hyaluron[-]säure-Molekülen in den Innenohrflüssigkei[-]ten hat gleichfalls einen Einfluss auf di[e] *cochleare Osmoregulation insofern* als di[e] Hyaluronsäure aufgrund ihrer zahlreiche[n] polaren Gruppen ein erhebliches Wasserbin[-]dungsvermögen besitzt. Marquet (1956) ver*mutete nach seinen klinischen Untersuchun*gen zur Hörstörung bei Hypothyreosen einen Hydrops der Cochlea der durch die experimentellen Ergebnisse indirekt bestätigt wer*den konnte Es handelt sich jedoch mit Si*cherheit nicht um einen endolymphatischen Hydrops wie man ihn als Ursache für den Morbus Menière ansieht – dafür bestehen bei der hypothyreotisch bedingten Schwerhörigkeit keinerlei Hinweise – aber mit hoher Wahrscheinlichkeit um einen Hydrops verschiedener Innenohrhohlräume dem konsequenterweise Elektrolytverschiebungen folgen können

Die angeführte elektrochemische Theorie für die Entstehung der Innenohrstörung im Rahmen der Schilddrüsenunterfunktion gewinnt u a. umso mehr an Wahrscheinlichkeit als die klinisch fassbaren Änderungen der Hörleistung durch eine Hormonsubstitution oftmals beseitigt werden können

Eine weitere Ursache der *Hörstörung* konnte durch pathologische Vorgänge im Bereiche des Ganglion *spirale und des N acusticus* mit seinen präganglionären und postgang

honkren Fasern zu suchen sein. Von de Vos (1963) wurde nach dessen Ergebnissen bei der Hypothyreose eine Degeneration von Ganglienzellen nachgewiesen worin der Autor die Ursache von Innenohrstörungen vermutet. Vergleicht man damit die histochemischen Ergebnisse zum *Enzymnachweis z. B.* der N Azetyl-Glukosaminidase in den Ganglienzellen des Ganglion scarpae so kann eine grob morphologische Schädigung der Zellen nicht in Betracht gezogen werden. Vielmehr scheint eine *Stoffwechseldrosselung*, die sich im Absinken der Fermentaktivität dokumentiert, im Vordergrund zu stehen. Nach autoradiographischen Untersuchungen haben die Ganglienzellen des *Ganglion spirale* den höchsten Eiweissumsatz von allen Innenohrstrukturen (Plester 1960: Meyer zum Gottesberge und Plester 1961 Koburg und Plester 1962*a b* Plester Koburg und Hempel 1962 Maurer und Koburg, 1964) und zwar nimmt die Umsatzrate von Aminosäuren in den Ganglienzellen von der Basalwindung zur Apikalwindung ab was möglicherweise mit der grösseren funktionellen Belastung der Basalwindung zusammenhängt (Koburg und Meyer zum Gottesberge 1964). *Die Inkorporation* von H_3-Aminosäuren in die Ganglienzellen nimmt zur Spitze hin etwa um 30% ab während die Resorptionsfähigkeit der Stria vascularis für ^{42}K eine Steigerung von der Basal zur Apikalwindung zeigt (Meyer zum Gottesberge Rauch und Koburg, 1965).

Man kann sich somit vorstellen dass die durch die Hypothyreose ausgelöste Herabsetzung der Proteinsynthese wie bereits angedeutet einen entscheidenden Einfluss auf die Funktionsfähigkeit der Ganglienzellen besitzt.

Zudem fällt ein zweiter Befund im Bereich des Nerven auf dem mutmasslich eine eher mechanisch erklärbare Bedeutung zukommt. In unmittelbarer Nähe des Nerven, in der Umgebung des Plexus cochlearis lassen sich häufig teilweise perjodatreaktive und/oder hyaluronidasesensitive Substanzen beobachten deren Auswirkung auf den Nerven hinsichtlich einer Funktionsbeeinträchtigung zwei *Interpretationsmöglichkeiten* zulassen. Es wäre denkbar dass durch das hohe Wasserbindungsvermögen der Hyaluronsäure ein hydropischer Zustand in der Umgebung des Nerven ausgelöst wird der zu Diffusionsstörungen der Schwannschen Zellen und damit zu einer Beeinträchtigung der Leitfähigkeit des Nerven führt. Darüberhinaus bestände die Möglichkeit, dass Nervanteile im knöchernen *Modiolus und besonders in den* Rosenthalschen Kanälchen der Lamina spiralis ossea durch die Hydropie des umgebenden Gewebes komprimiert werden. So würde eine Störung der Reizleitung als Sekundärfolge der Hydropie im Bereich des Möglichen liegen. Ein *Phänomen* welches auch als Ursache für die sog. Bell'sche Facialislähmung diskutiert wird.

Zuletzt erhebt sich die Frage auf welchem Wege die sauren Mukosubstanzen sowie Muko- und Glukoproteide in die -skalen des Innenohres gelangen und auf welche Weise diese die Peri und Endolymphräume wieder verlassen. Bevor verschiedene Möglichkeiten des Stofftransportes diskutiert werden sollen muss *festgestellt werden, dass auch heute noch keine vollständige Klärung dieses Problems* herbeigeführt werden konnte. Insgesamt gesehen besitzt der Ductus cochlearis mit seinen spezialisierten Wandabschnitten sezernierende und resorbierende Funktionen. Als hypothetischer Bildungsort für die Endolymphe werden die Stria vascularis Sulcus spiralis externus, Prominentia spiralis Liquor cerebrospinalis Reissner Membran (aus der Perilymphe) angenommen wofür mancherlei Gründe sprechen die hier nicht näher erörtert werden können (Lit. s. Rauch, 1964). Die Resorption der Endolymphe scheint überwiegend im Saccus endolymphaticus zu erfolgen ist aber wohl auch in der Stria vascularis möglich die einen *entsprechenden morphologischen* Aufbau mit erheblicher Vergrösserung der Oberfläche *zur Endolymphe hin auf*weist. Die Entstehung der Perilymphe lässt nach *Werner (1940)* drei Möglichkeiten zu 1 *aus dem Liquor* cerebrospinalis, 2. aus Ge-

Bedeutung der Elektrolyte für die Hörfunktion muss sehr hoch eingeschätzt werden da die hydrostatischen und energetischen Funktionen in direktem Zusammenhang mit der normalen Elektrolytverteilung in der Innenohrflüssigkeit stehen

Donnan (1911) konnte zeigen dass sich frei diffundierende Elektrolyte zweier durch eine Membran getrennter Flüssigkeiten ungleich verteilen wenn auf der einen Seite nicht diffusible Elektrolyte vorliegen d h wenn auf der einen Seite nicht diffusible Stoffe mit hoher Ionenbindungskraft wie z B Mukopolysaccharide vorhanden sind Aus diesen Gesetzmässigkeiten würde sich ableiten lassen dass im vorliegenden Fall auf der Seite der negativ geladenen Polyelektrolyte (MPS) die Konzentration diffusibler Elektrolyte am höchsten ist.

Nun hat die Membrana tectoria einen hohen Gehalt an sauren Mukopolysacchariden worauf Belanger (1953) Dohlmann (1960) Dohlmann et al (1959) Dohlmann und Ormerod (1960) aufgrund ihrer autoradiographischen Arbeiten hinwiesen Über die Polyelektrolytwirkung der Mukopolysaccharide der Membrana tectoria berichteten wie schon erwähnt Vilstrup und Jensen (1954) Jensen Koefoe und Vilstrup (1954) Die Mukopolysaccharide wirken sich also im Donnan Gleichgewicht in der Beziehung zwischen Peri und Endolymphe aus Nach alledem kann diskutiert werden ob nicht ein passiver Wasser und Ionentransport von der Perilymphe über die Endolymphe zum Gefässsystem möglich ist (s auch Rauch 1964)

In diesem Zusammenhang gewinnen die experimentell erhobenen Befunde zur Verteilung der Mukopolysaccharide in den Innenohrstrukturen bei der Hypothyreose erhebliches Interesse Durch die Anhäufung von histochemisch nachweisbaren sauren Mukopolysacchariden in den verschiedenen Skalen der Cochlea insbesondere im Bereich der Scala vestibuli und tympani wird nach den Gesetzmässigkeiten des Donnan-Gleichgewichts eine Diffusion von Kaliumionen von der Endolymphe zu den anionischen Polyelektrolyten in der Perilymphe stattfinden also eine gegensätzliche Richtung des vermuteten Flüssigkeitsstromes von der Perilymphe in die Endolymphe Infolge dieser Kaliumverschiebung wird das für den normalen Hörvorgang wichtige Kaliumionen Natriumionen-Verhältnis in Endo- und Perilymphe verschoben Ausserdem kann es durch zusätzliche Ablagerungen von sauren MPS in der Scala media zu einer Vermehrung von negativen Polyelektrolyten kommen denn man muss berücksichtigen dass die Membrana tectoria ebenfalls einen hohen Gehalt an sulfatierten Mukopolysacchariden aufweist

Die vermehrte Ansammlung von Hyaluronsäure Molekülen in den Innenohrflüssigkeiten hat gleichfalls einen Einfluss auf die cochleare Osmoregulation insofern als die Hyaluronsäure aufgrund ihrer zahlreichen polaren Gruppen ein erhebliches Wasserbindungsvermögen besitzt Marquet (1956) vermutete nach seinen klinischen Untersuchungen zur Hörstörung bei Hypothyreosen einen Hydrops der Cochlea der durch die experimentellen Ergebnisse indirekt bestätigt werden konnte Es handelt sich jedoch mit Sicherheit nicht um einen endolymphatischen Hydrops wie man ihn als Ursache für den Morbus Menière ansieht – dafür bestehen bei der hypothyreotisch bedingten Schwerhörigkeit keinerlei Hinweise – aber mit hoher Wahrscheinlichkeit um einen Hydrops verschiedener Innenohrhohlräume dem konsequenterweise Elektrolytverschiebungen folgen können

Die angeführte elektrochemische Theorie für die Entstehung der Innenohrstörung im Rahmen der Schilddrüsenunterfunktion gewinnt u a. umso mehr an Wahrscheinlichkeit als die klinisch fassbaren Änderungen der Hörleistung durch eine Hormonsubstitution oftmals beseitigt werden können

Eine weitere Ursache der Hörstörung könnte durch pathologische Vorgänge im Bereiche des Ganglion spirale und des N acusticus mit seinen präganglionären und postganglionären

möglichkeit für eine verzögerte Rückresorption der MPS aus der Perilymphe.

Die in der *Endolymphe histochemisch* bestimmten MPS werden mutmasslich zu einem grossen Teil im Saccus endolymphaticus resorbiert zumal sich aus den experimentellen Ergebnissen eine Anhäufung saurer Mukosubstanzen in der Saccuslichtung bestimmen lässt. Eigene autoradiographische Untersuchungen am Saccus endolymphaticus erbrachten eine hohe Inkorporationsrate für H_3-markierte Aminosäuren, die sich besonders in den Epithelien der Pars intermedia sowie im subepithelialen Raum und in einigen der sog. freien Zellen dokumentierte. In Anlehnung an die grundlegenden Arbeiten von Guild (1927 a, b) sowie Publikationen von Mygind (1948), Altmann und Waltner (1950), Saxén (1951), Arnvig (1951), Lundquist et al. (1964 a, b), Lundquist (1965) wurden zwei „phagocytierende Systeme" im S. e. angenommen: die Pars intermedia und die sog. freien Zellen (Haubrich und Koburg, 1966; Koburg et al. 1967). *Erwartungsgemäss besitzen Zellen*, die für einen aktiven Stofftransport, wie sie die Resorption darstellt, einen hohen Eiweissumsatz, der in diesen Experimenten bestätigt wurde. Rudert (1969 a, b) brachte radioaktiv markiertes Meerschweinchenеiweiss sowie H_3-Aminosäuren (Lysin, Glycin) in den Ductus cochlearis ein und beobachtete anschliessend die Resorption in den Epithelien der Pars intermedia und in den Zellen des darunterliegenden Bindegewebes. In Übereinstimmung zu den autoradiographischen Befunden wiesen Schätzle und Haubrich (1966) eine hohe Fermentaktivität in der Pars intermedia der S. e. und in den sog. freien Zellen nach. Eine besonders starke Aktivität zeigte die *N-Azetyl-Glukosaminidase und* unspezifische Esterase. Beide Fermente nahmen unter *Mangel an Schilddrüsenhormonen* ab. Vielleicht ein weiteres Indiz für den verzögerten Abbau und die behinderte Rückresorption der Mukopolysaccharide in den beschriebenen Strukturabschnitten des Saccus endolymphaticus.

Die am hypothyreoten Meerschweinchen erzielten Untersuchungsergebnisse eröffnen sektorförmig einen Einblick in die morphologisch nachweisbaren Strukturalterationen des Innenohres, die einige neue Erkenntnisse zur Entstehung der *Schallperzeptionsstörung* unter *Schilddrüsenhormonmangel vermitteln*, andererseits aber auch weitere *Fragen aufkommen lassen*, die durch elektrophysiologische und biochemische Arbeitsmethoden vielleicht beantwortet werden können. Am Schluss *soll eine Zusammenfassung der Befunde* und ihrer Interpretationsmöglichkeiten dargestellt werden.

a) Das im Vordergrund stehende pathomorphologische-histochemische Substrat ist die *Ablagerung von hyaluronidasesensitiven metachromotropen* Mukosubstanzen in den verschiedenen Skalen des Innenohres und im Bereich des Plexus cochlearis in unmittelbarer Nachbarschaft des N. acusticus. Durch die Anhäufung von sauren MPS kann sich infolge des hohen Wasserbindungsvermögens dieser *Substanzen ein allgemeiner Hydrops des Innenohres entwickeln. Zum anderen werden durch die anionische Polyelektrolytwirkung* der sauren MPS Verschiebungen von Kalium- und Natriumionen zwischen Peri- und Endolymphe möglich, deren normale Relation eine wichtige Voraussetzung für den normalen *Hörvorgang darstellt*.

Durch die Anhäufung saurer Mukosubstanzen mit grösseren *Koacervaten* in unmittelbarer Nähe des N. acusticus *kann dieser komprimiert werden*, besonders in den sehr dünnen Rosenthalschen *Kanälchen*, was *zu einer* Behinderung des notwendigen „axonal flow" aus der *Ganglienzelle* in das zugehörige Axon führt und damit einer Funktionsbeeinträchtigung Vorschub leistet. Zudem wird sich die Hydropie des umgebenden Gewebes im Bereiche des Nerven in einer Diffusions*störung* für den Stoffwechselaustausch *der* Schwannschen Zellen negativ bemerkbar machen.

Letztlich *erhält* die Anhäufung saurer Mukosubstanzen *im* Bereiche des Tractus arteriosus *et venosus* (Plexus cochlearis) Beweis-

fässen der Perilymphräume 3 aus der Endolymphe. Die meisten Untersuchungen sprechen für eine Produktion der Perilymphe aus den zahlreichen die Perilymphräume umgebenden Gefässe Eine ausführliche literaturhistorische Darstellung der verschiedenen Hypothesen über Sekretion und Resorption von Innenohrflüssigkeiten hat Rauch (1964) gegeben

Die in unmittelbarer Nähe des Plexus cochlearis (Balogh und Koburg, 1965) mit seinem Tractus spiralis arteriosus und venosus gelegenen hyaluronidasesensitiven Mukosubstanzen lassen sich aufgrund der autoradiographischen und fermenthistochemischen Untersuchungen (s auch Schätzle und v Westernhagen 1968) in Entstehung und Weitertransport gut erklären Nach Meinung von Balogh und Koburg findet sich im Plexus cochlearis ein sehr hoher Eiweissumsatz der bei manchen Tieren mit der Höhe der Umsatzraten in Ganglienzellen des Ganglion spirale vergleichbar ist Zudem entspricht der hohen Inkorporationsrate an H_3-Aminosäuren eine reiche Fermentausstattung mit DPNH und TPNH sowie LDH Morphologische und stoffwechseldynamische Vergleiche verschiedener Strukturen deren leptomeningeale Herkunft gesichert erscheint (z B Aderhaut des Auges Plexus chorioideus) mit dem Plexus cochlearis lassen weitgehende Übereinstimmung erkennen Balogh und Koburg nahmen daher eine sekretorische Funktion dieses stark ausgebildeten Gefässplexus an wofür eindrucksvoll die festgestellten Ansammlungen von Mukopolysacchariden in der unmittelbaren Umgebung des Plexus sprechen

Der Weitertransport der MPS vom Plexus cochlearis dürfte entlang de Nerven über das Ganglion spirale bi zu d n Sinneszellen möglich sein ein Weg den Jampolski (1935) Kley (1951) und Svane Knudsen (1958) für möglich hielten Die sauren MPS können somit vermehrt in den Tunnelraum hineingelangen dessen früher als Cortilymphe bezeichneter Inhalt nach elektronenmikroskopischen Untersuchungen von Ilberg (1968*b*) identisch mit der Perilymphe ist d h es handelt sich um eine natriumreiche und kaliumarme Flüssigkeit Man kann also davon ausgehen dass eine freie Kommunikation des sog Cortilymphraumes mit der Scala tympani über die Habenula perforata entlang der Nervenfasern bis zu den inneren Haarzellen existiert Ein zweiter Transportweg ergibt sich aus den Untersuchungen von Ilberg über die Scala tympani die ja in Verbindung mit der Scala vestibuli steht so dass auch aus diesem Perilymphraum saure Mukosubstanzen in den Cortilymphraum gelangen können.

Die Produktion der MPS in die perilymphatischen Räume dürfte über das reich entfaltete Gefässystem der perilymphatischen Skalen vor sich gehen umsomehr als bei der Hypothyreose eine Erhöhung der Mukopolysaccharide im Blutserum bekannt ist

Nach experimentellen Untersuchungen von Ilberg (1968*a*) ist bewiesen dass über das Ligamentum spirale mit seinen breiten Interzellularräumen beide Skalen miteinander kommunizieren das Bindegewebe des Lig. spirale quasi einen grossen Schwamm darstellt der von Perilymphe durchdrungen wird eine Vorstellung, die von Tonndorf et al (1962) Spoendlin und Balogh (1964) Cimino und Grisanti (1967) Ilberg (1968*a*) Vosteen (1970) entwickelt wurde Aus dieser Verbindung beider Skalen wird die Verteilung der Mukosubstanzen in allen perilymphatischen Räumen verständlich

Die Resorption der Makromoleküle wie sie die Mukopolysaccharide darstellen könnte nach fermentativer Aufspaltung der Mukosubstanzen erfolgen Voraussetzung ist eine ungestörte für die MPS substratspezifische Fermentaktivität die bei den experimentellen Untersuchungen am Beispiel der β-Galaktosidase der β-Glukuronidase und N Azetyl Glukosaminidase dargestellt wurde Während die ersten beiden Glykosidasen in ihrer Aktivität im Gewebe gegenüber den Kontrolltieren weitgehend unverändert sind nimmt die Glukosaminidase sehr deutlich ab Vielleicht wäre diese Tatsache u a eine Erklärungs

11 Zusammenfassung

Seit langer Zeit ist Schwerhörigkeit als fakultatives oder obligates Symptom bei Schilddrüsenerkrankungen bekannt, ohne dass bislang eindeutige morphologische Befunde zur Deutung der Hörminderung erhoben worden sind. Zu experimentellen morphologischen Studien werden 70 thyreoidektomierte Meerschweinchen verwendet, die als Modell für die primäre Hypothyreose infolge quantitativer Störung der Hormonbildung beim Menschen gelten können. Nach Tötung der Tiere in verschiedenen Zeitabständen werden mit histochemischen Methoden verschiedene Glykosidasen (β-Galaktosidase, β-Glukuronidase, N-Azetyl-β-Glukosaminidase) sowie unspezifische Esterasen und Aryl-Sulfatasen, Sulfhydryl-Gruppen und Mukosubstanzen in der Cochlea und im Saccus endolymphaticus bestimmt. Folgende Ergebnisse lassen sich erheben: Durch Ablagerung von hyaluronidasesensitiven metachromotropen Mukosubstanzen in den Skalen des Innenohres wird mutmasslich das Verhältnis Kaliumionen zu Natriumionen in Endolymphe und Perilymphe infolge der anionischen Polyelektrolytwirkung der sauren Mukopolysaccharide gestört. Darüberhinaus kommt es zu einem Hydrops der verschiedenen Innenohrhohlräume durch die stark hydropen Eigenschaften der sauren MPS mit konsekutiver Verschiebung der Elektrolytverhältnisse (Elektrochemische Theorie). Die in der Umgebung des N. acusticus angehäuften sauren MPS können infolge der Hydropie zu Kompressionserscheinungen des Nerven besonders in den Rosenthalschen Kanälchen der Lamina spiralis ossea führen (mechanische Theorie). Einzelne Enzyme (unspezifische Esterase, N-Azetyl-β-Glukosaminidase) werden in ihrer Aktivität in verschiedenen Abschnitten der Cochlea und des Saccus endolymphaticus durch den Hormonmangel beeinträchtigt, was auf die fermentinduktive Eigenschaft der Schilddrüsenhormone bezogen werden kann.

Die Vermehrung der sauren MPS in den verschiedenen Skalen der Cochlea und des Saccus endolymphaticus lässt sich aus einer vermehrten Produktion und einer verminderten Resorption der Stoffe erklären, wofür auch die Ansammlung metachromotropen Materials im S. e. spricht. Nach den morphologischen Ergebnissen lässt sich zumindest ein Sekretionsort der sauren MPS im Bereich des Plexus cochlearis lokalisieren. Alle angegebenen Befunde können eine Erklärung für die häufiger anzutreffende Innenohrschwerhörigkeit geben. Die seltenere Schalleitungsstörung dürfte auf eine myxomatöse Veränderung der Mittelohrschleimhaut mit konsekutiver Versteifung der Gehörknöchelchen zu beziehen sein. Letztlich wird aus den Befunden die teilweise Reversibilität der Schwerhörigkeit nach Hormonsubstitution verständlich.

kraft für das sekretorische Leistungsvermögen dieser Innenohrstruktur

b) Ein weiteres Merkmal hypothyreotisch bedingter Störung des Innenohrstoffwechsels ist der erhobene Enzymstatus der unspezifischen Esterasen Aryl Sulfatasen und Glykosidasen Insgesamt sind die Befunde diskreter als beim Stoffwechselmetabolismus der Mukosubstanzen So werden mehr die Aktivitäten der unspezifischen Esterase und die N Azetyl-Glukosaminidase reduziert als die der Glukuronidase und Galaktosidase Die Aktivitätsbeeinträchtigung der Fermente dürfte im Zusammenhang der enzyminduktiven Wirkung der Schilddrüsenhormone und der herabgesetzten Proteinsynthese bei der Hypothyreose zu sehen sein Mit entscheidend scheint die stark verminderte Aktivität der Glukosaminidasen zu sein die für einen Hauptbestandteil der sauren MPS des N Azetyl-Glukosamin substratspezifisch ist

Wenn auch die Bedeutung der dargestellten Fermente für die Funktionen des Innenohres noch weitgehend ungeklärt ist wird jedoch eine Störung des Fermenthaushaltes nicht ohne Folgen für die Funktion bleiben können

c) Die Produktion und Resorption der Mukopolysaccharide in den Innenohrräumen lassen sich aufgrund der heutigen Ansichten über aktive und passive Leistung der für den Stofftransport spezialisierten Wandbestandteile des Ductus cochlearis und der beiden perilymphatischen Skalen deuten Ein sicherer Weg der Produktion dürfte am Plexus cochlearis über die Nervenfasern in den sog Cortilymphraum und damit zu der Basis der Haarzellen verlaufen Andere Wege liegen mit grosser Wahrscheinlichkeit ebenfalls vor wie sich aus den Erörterungen zur Sekretion und Resorption der Innenohrflüssigkeiten entnehmen lässt Die Resorption der Mukopolysaccharide aus der Scala media geht wahrscheinlich zu einem Grossteil über den Saccus endolymphaticus in dem alcianblaues, hyaluronidasesensitives Material festgestellt worden ist Es ist durchaus denkbar dass die Resorption infolge einer verzögerten Aufschlusselung der MPS durch die herabgesetzte Fermentaktivität in ihrem Geschwindigkeitsablauf beeinflusst wird

d) Durch die myxomatöse Verdickung der Mittelohrschleimhaut die nach experimentellen und klinischen Ergebnissen relativ selten vorkommt lässt sich zwanglos infolge von Versteifung der Gehörknöchelchen eine resultierende Schalleitungsstörung erklären

Alle Veränderungen haben nur Gültigkeit in der Übertragung auf den Menschen bei der im Kindes oder Erwachsenenalter erworbenen Hypothyreose infolge qualitativ gestörter Hormonbildung Sie besitzen keine Aussagekraft für die Genese der endemischen Hörstörung oder des sog Pendred Syndrom Sie berücksichtigen auch nicht die durchaus möglichen hypothyreotisch bedingten zentralen Störungen Die Untersuchungen sind jedoch erste Schritte in der Aufklärung hormoneller Einflüsse auf das Innenohr soweit sie mit morphologischen Methoden fassbar sind Sie können eine Erklärung für die oft zu beobachtende Reversibilität der Innenohrstörungen nach Hormonsubstitution geben

12 Summary

It has been known for a long time that hearing deficits may coexist in patients with thyroid disease but without definite morphologic evidence present to correlate gland dysfunction with hearing disturbances To clarify this relationship between thyroid dysfunction and hearing disturbances the guinea pig was employed as an experimental model 70 animals were thyroidectomized and maintained in a hypothyroid state for varying periods of time The animals were then sacrificed and various histochemical studies then performed These studies included analysis for glycosidase (β-galactosidase β-glucuronidase n acetyl β-glucosamide) non specific esterases sulfatases sulfhydryl groups as well as mucous substances within the cochlea and saccus endolymphaticus of the experimental animals Results indicated that hyaluronidase sensitive mucous substances were increased in the scala of the inner ear As a consequence of increased deposition of acid mucopolysaccharides the relationship of potassium to sodium in endolymph and perilymph was found markedly altered Marked swelling of the chambers of the inner ear was noted and believed to represent hydropic induction by acid mucopolysaccharide—with consequent alteration of electrolyte relationships (Electrochemical Theory)

Acid mucopolysaccharide was also found in significant quantities in the region of the acoustic nerve producing a compression phenomenon of the nerve This was most marked in the region of Rosenthal s canal of the lamina spiralis ossea. This *finding supports* a Mechanical Theory for hearing disturbance Lowered levels of enzymes (non specific esterases n acetyl β-glucosamidase) were found in the cochlea and saccus endolymphaticus and were attributed to lack of thyroid hormone initiating enzyme activity

The increase in acid mucopolysaccharide in the different scala of the cochlea and saccus endolymphaticus was explainable by both increased production and altered resorption These factors were also in evidence by the collections of metachromatic granules in the saccus endolymphaticus A secretory site for acid mucopolysaccharide was uncovered in the region of the plexus cochleans.

Findings during the present investigation provided morphologic evidence for inner ear disease in association with thyroid dysfunction Also noted during the present study was myxomatous change in the middle ear mucosa with consequent suffening of the ossicles Thus both neurosensory and conductive hearing losses could be explained by the present findings

Replacement hormone therapy was given to a group of the experimental animals and was found to modify the previously noted changes in the inner and middle ears

The present study has indicated that thyroid dysfunction can result in hearing disturbances in experimental models Further work will be performed to further define this relationship in both experimental and clinical levels of endeavor

UPPSALA 1973

Introduction

The dependence of receptor organs on their nervous connections has been extensively studied throughout the century since Ranvier (1875) found that taste buds disintegrate after the section of gustatory nerves. A review of the results of experimental work on different types of receptors after peripheral nerve degeneration and regeneration was presented by Zelená (1964). The receptor organs investigated were of both the primary (cutaneous and muscle receptors) and the secondary type (taste buds and lateral-line organs). In all these sensory cells signs of degeneration were found after denervation, and in many cases regeneration was induced by reinnervation. The evidence was consistent with the hypothesis that nerve endings exert a trophic effect on the maintenance and eventually on the differentiation of receptor organs.

In the case of the lateral-line system, degeneration of sensory cells at various periods after transection of the nerves, followed by reinnervation and regeneration, has been reported by several authors, though others have asserted that denervation does not necessarily result in complete loss of sensory organs. Earlier studies on lateral line organs in amphibia were reviewed by Wright (1951), who concluded that this sensory system can persist for months after repeated nerve section. The effect of denervation in long-term experiments was considered to consist of a decrease in the size of the denervated organs by a regressive process involving atrophy, dedifferentiation and eventually total degeneration of the whole organ. This suggests that the nerve exerts a definite trophic action on these sensory organs but that the effect of its removal is not immediate but long-term. This is consistent with the results of Speidel's research on frog tadpoles (1964).

As far as the vestibulo-cochlear system is concerned, there is little information available about the fate of vestibular sensory cells after lesions of the nerves. A recent study in squirrel monkey (Igarashi & Miata, 1972) indicates that degeneration of the crista sensory epithelium occurs after sectioning of more than 75% of the ampullar nerve. Gribenski (1963) reported advanced crista degeneration one month after destruction of the ganglion of Scarpa in frog. The organ of Corti in cat remains intact for several months after sectioning of the cochlear nerve (Spoendlin & Gacek, 1963); this finding is discussed later in the light of recent findings by Spoendlin (1971).

In a number of studies of the effects of nerve division in the vestibulo-cochlear system interest has been centred chiefly on the relations between afferent and efferent fibres as disclosed by light and electron microscopy (Rasmussen & Gacek, 1958; Schuknecht et al., 1959; Gacek, 1960; Kimura & Wersäll, 196.., Smith & Rasmussen, 1963, 1965, 1968; Spoendlin, 1966, 1971). Robbins et al., (1967) demonstrated the existence of efferent nerve fibres to the labyrinthine sensory areas in the bullfrog in a study of the degeneration of fibres in the transected vestibular nerve. Hillman (1969) found efferent nerve fibres connecting the cerebellum and brainstem nuclei with the sensory cells of the macula sacculi in the frog. The effect of cutting the vestibular nerve on the sensory cells was not described in this report. A tendency for complete morphological and functional restoration after dividing the vestibular nerve in frogs was observed earlier by Sperry (1945).

After transposing nerves from one ampulla of the labyrinth to another in the frog, Gribenski (1963) found a regeneration from one nerve to a different end organ, and followed the physiological effect of this transformation of ampullar nerve fibres. Even today little is known about the

Printed in Sweden by

The present study was undertaken to examine (1) the effect of division of peripheral ampullar nerves on the fine structure of synapses and sensory cells (2) the capacity of the nerve fibres to regenerate under various experimental conditions and (3) the structural changes that occur in the sensory cells after denervation and during reinnervation.

Material and Methods

The study was performed on the adult frog (*Rana temporaria*). The normal anatomy of the labyrinth of this species is similar to that of the bullfrog as described by Geisler et al. (1964). Thus the anterior branch of the vestibular nerve gives off separate branchlets to the anterior vertical and horizontal cristae, and the maculae of the utricle and saccule. This part of the labyrinth is readily accessible for experimental work.

Two sets of experiments were performed. In one set one or both ampullar nerves were sectioned and the nerves, synapses and sensory cells were examined at intervals during the degenerative phase and during regeneration of the nerve fibres. In the second set of experiments the two ampullar nerves were divided and the proximal stump of the horizontal nerve was brought into contact with the distal end of the anterior vertical nerve. In one case the anterior nerve was actually attached to the horizontal distal stump. The operations are shown schematically in Fig. 1. Twenty animals survived the surgical procedure without apparent complications and could be followed until the labyrinths were fixed *in vivo* and submitted to histological examination. In a few other specimens there were post-operatively signs of loss of function of most or all parts of the labyrinths subjected to limited surgery. Some of these animals died after a few days. In such cases inflammatory cells invading the endolymphatic spaces and the surrounding tissues were found on microscopical examination, and these animals were excluded. Other animals survived for long period and their physiological responses could be tested during the course of the postoperative period but, because of spontaneous death at later stages, they were also excluded from electron microscopical examination as post-mortem changes were likely to interfere with signs of intravital degeneration.

Operative Procedures

The ampullar nerves were exposed in the curarized frog (2–3 mg of *d*-tubo-curarine per kg body weight) which was kept moistened. The operation was carried out as described by McNally & Tait (1933) and Gribenski (1963): thus the mucosa of the palate was incised, part of the chondrous capsule of the labyrinth was removed and the bone capsule was drilled away over the anterior branch of the nerve in the region of the cristae. The endosteum and the membrane limiting the perilymphatic space were incised. The nerves to the anterior vertical and the horizontal

relation between the nerve endings and the sensory cells during degeneration and regeneration of nerve fibres in the vestibular system

In a series of studies, Sperry has examined the relation between certain central nuclei and peripheral end-organ on the one hand and on the other the ability of afferent nerve fibres to regenerate and restore the normal functional relationship between the end organ and the central nervous system. The results suggest that a chemoaffinity is the basic mechanism regulating the growth and organization of nerve fibres and their connections (Sperry 1963) Weiss (1955) considered it possible that there is some reorganization through an influence from the periphery upon more central portions of the nervous system during the regeneration phase Together with Pillai (1965) he also studied the ultrastructural changes in axons in which constrictions were made to prevent the proximo-distal displacement of axonal contents first described by Cajal (1928) and later by Weiss & Hiscoe (1948) It has later been shown by different methods that transport of several axonal components occurs in both directions and at different velocities (see e.g. Lubińska 1964 Grafstein 1969) Although the substances which exert the presumed neurotrophic effect on other nerves or end organs have not been identified, there is accumulating evidence for a nutritive and regulatory role of axonal transport mechanisms as a basis for such an hypothesis The incitement to the present study was provided by Gribenski's above mentioned studies on frogs (1963) in which the functional results of labyrinthine experiments are described The behavioural physiology of the vestibular apparatus in frog was elucidated long ago by Tait & McNally (1925) by means of simple rotatory sliding and tilting tests, and the roles played by the different sensory formations in the labyrinth were shown by selective ablation experiments (McNally & Tait, 1925 and 1933). The results were confirmed by Gribenski who in 1963 published a review of the earlier work, together with a summary of a series of experiments of his own on the function of the semicircular canals of the frog. Electrophysiological studies on these organs were made by Ledoux who recorded afferent mass potentials from the ampullar nerves and tried to correlate the results of clinical vestibular tests with the patterns of peripheral nerve activity following different stimuli (Ledoux, 1958)

Gribenski completed his studies with a series of animals in which nerves from one ampulla were transposed to another resulting in misdirected reflexes after the inappropriate reinnervation This experiment is briefly described here together with some of the basic physiological responses to stimulation

In a normal frog rotatory acceleration in the horizontal plane leads to a perstimulatory deviation of the head and an incurvation of the body in the sense opposed to the rotation the post stimulatory reaction is reversed On tilting forwards through a transversal axis, the animal reacts by extending its arms and raising its head this position is maintained when the tilting is stopped. After elimination of the function of the left horizontal ampulla, the animal does not turn its head to the left on horizontal rotatory accelerations the deviations to the right are quite normal After elimination of the function of the left anterior vertical ampulla, the frog reacts on tilting forwards by dipping its head downwards to the left with a torsion of the spine owing to inadequate extension of the left arm and to increased extension of the right leg, when the tilting is stopped a normal pose for that inclination is assumed When Gribenski let the left horizontal nerve innervate the anterior vertical ampulla (after operation R" derived from the word régénération) a new reaction (reaction R") was found on tilting about 2 weeks after the operation The head then deviated to the right side and by repeated accelerations causing endolymph movement in the vertical canals, the animal incurved and sometimes began to walk to that side All these reactions are interpreted as being due to an increase in impulse activity in the left horizontal nerve activated from the reinnervated anterior vertical crista This reaction reaches a maximum at about 3–4 weeks after the operation

The present study was undertaken to examine (1) the effect of division of peripheral ampullar nerves on the fine structure of synapses and sensory cells (2) the capacity of the nerve fibres to regenerate under various experimental conditions and (3) the structural changes that occur in the sensory cells after denervation and during reinnervation.

Material and Methods

The study was performed on the adult frog (*Rana temporaria*). The normal anatomy of the labyrinth of this species is similar to that of the bullfrog as described by Geisler et al. (1964). relation between the nerve endings and the sensory cells during degeneration and regeneration of nerve fibres in the vestibular system

In a series of studies, Sperry has examined the relation between certain central nuclei and peripheral end-organ on the one hand and on the other the ability of afferent nerve fibres to regenerate and restore the normal functional relationship between the end organ and the central nervous system. The results suggest that a chemoaffinity is the basic mechanism regulating the growth and organization of nerve fibres and their connections (Sperry, 1963). Weiss (1955) considered it possible that there is some reorganization through an influence from the periphery upon more central portions of the nervous system during the regeneration phase. Together with Pillai (1965) he also studied the ultrastructural changes in axons in which constrictions were made to prevent the proximo-distal displacement of axonal contents first described by Cajal (1928) and later by Weiss & Hiscoe (1948). It has later been shown by different methods that transport of several axonal components occurs in both directions and at different velocities (see e.g. Lubińska, 1964; Grafstein, 1969). Although the substances which exert the presumed neurotrophic effect on other nerves or end organs have not been identified, there is accumulating evidence for a nutritive and regulatory role of axonal transport mechanisms as a basis for such an hypothesis. The incitement to the present study was provided by Gribenski's above-mentioned studies on frogs (1963) in which the functional results of labyrinthine experiments are described. The behavioural physiology of the vestibular apparatus in frog was elucidated long ago by Tait & McNally (1925) by means of simple rotatory, sliding and tilting tests, and the roles played by the different sensory formations in the labyrinth were shown by selective ablation experiments (McNally & Tait, 1925 and 1933). The results were confirmed by Gribenski who in 1963 published a review of the earlier work, together with a summary of a series of experiments of his own on the function of the semicircular canals of the frog. Electrophysiological studies on these organs were made by Ledoux who recorded afferent mass potentials from the ampullar nerves and tried to correlate the results of clinical vestibular tests with the patterns of peripheral nerve activity following different stimuli (Ledoux, 1958).

Gribenski completed his studies with a series of animals in which nerves from one ampulla were transposed to another, resulting in misdirected reflexes after the inappropriate reinnervation. This experiment is briefly described here together with some of the basic physiological responses to stimulation.

In a normal frog rotatory acceleration in the horizontal plane leads to a perstimulatory deviation of the head and an incurvation of the body in the sense opposed to the rotation; the poststimulatory reaction is reversed. On tilting forwards through a transversal axis, the animal reacts by extending its arms and raising its head; this position is maintained when the tilting is stopped. After elimination of the function of the left horizontal ampulla, the animal does not turn its head to the left on horizontal rotatory accelerations; the deviations to the right are quite normal. After elimination of the function of the left anterior vertical ampulla, the frog reacts on tilting forwards by dipping its head downwards to the left with a torsion of the spine owing to inadequate extension of the left arm and to increased extension of the right leg; when the tilting is stopped a normal pose for that inclination is assumed. When Gribenski let the left horizontal nerve innervate the anterior vertical ampulla (after operation "R", derived from the word *régénération*) a new reaction (reaction "R") was found on tilting about 2 weeks after the operation. The head then deviated to the right side and, by repeated accelerations causing endolymph movement in the vertical canals, the animal incurved and sometimes began to walk to that side. All these reactions are interpreted as being due to an increase in impulse activity in the left horizontal nerve activated from the reinnervated anterior vertical crista. This reaction reaches a maximum at about 3–4 weeks after the operation.

The present study was undertaken to examine (1) the effect of division of peripheral ampullar nerves on the fine structure of synapses and sensory cells (2) the capacity of the nerve fibres to regenerate under various experimental conditions and (3) the structural changes that occur in the sensory cells after denervation and during reinnervation.

Material and Methods

The study was performed on the adult frog (*Rana temporaria*). The normal anatomy of the labyrinth of this species is similar to that of the bullfrog as described by Geisler et al. (1964). Thus the anterior branch of the vestibular nerve gives off separate branchlets to the anterior vertical and horizontal cristae, and the maculae of the utricle and saccule. This part of the labyrinth is readily accessible for experimental work.

Two sets of experiments were performed. In one set one or both ampullar nerves were sectioned and the nerves, synapses and sensory cells were examined at intervals during the degenerative phase and during regeneration of the nerve fibres. In the second set of experiments the two ampullar nerves were divided and the proximal stump of the horizontal nerve was brought into contact with the distal end of the anterior vertical nerve. In one case the anterior nerve was actually attached to the horizontal distal stump. The operations are shown schematically in Fig. 1. Twenty animals survived the surgical procedure without apparent complications and could be followed until the labyrinths were fixed *in vivo* and submitted to histological examination. In a few other specimens there were post-operatively signs of loss of function of most or all parts of the labyrinths subjected to limited surgery; some of these animals died after a few days. In such cases inflammatory cells invading the endolymphatic spaces and the surrounding tissues were found on microscopical examination, and these animals were excluded. Other animals survived for long periods and their physiological responses could be tested during the course of the postoperative period but, because of spontaneous death at later stages, they were also excluded from electron microscopical examination as post mortem changes were likely to interfere with signs of intravital degeneration.

Operative Procedures

The ampullar nerves were exposed in the curarized frog (2–3 mg of *d*-tubo-curarine per kg body weight) which was kept moistened. The operation was carried out as described by McNally & Tait (1933) and Gribenski (1963); thus the mucosa of the palate was incised, part of the chondrous capsule of the labyrinth was removed and the bone capsule was drilled away over the anterior branch of the nerve in the region of the cristae. The endosteum and the membrane limiting the perilymphatic space were incised. The nerves to the anterior vertical and the horizontal [illegible]

cristae were isolated from the accompanying vessels and one or both nerves were divided, depending on the type of experiment. In one set of experiments the proximal stump was left in contact with the distal stump while in the other one of the proximal stumps was transposed to the distal stump of the other ampullar nerve. In order to increase the distance between the two stumps in the transposition experiments, the distal stump that should not reinnervate the crista was displaced and deflected proximally. The mucosal flap was applied and sutured over the operation cavity.

The frogs were then kept at room temperature (about 20 C) for varying periods. The animals surviving the procedure generally regained motility in a few hours. During the survival period they were kept moistened in small boxes, and fed with meal worms.

The function of the vestibular system was examined by rotatory and tilting tests at various, repeated intervals after the operation; the methods used were principally those of McNally & Tait (1925, 1933) and Gribenski (1963). In the rotatory tests optokinetic stimuli were eliminated by placing the animals in a cylindrical non-transparent box placed on a turn table. In tests of the function of the anterior vertical cristae repeated tipping movements were made, causing utriculo-fugal endolymphatic streaming. These physical stimuli and the animal's responses were rated in a roughly standardized way without attempt to strict quantitative measurements. At intervals of between 6 hours and 46 days after the operation the animal was again curarized, the labyrinth was opened, the anatomy of the operation wound was examined, and the labyrinth was fixed *in situ* with ice-cold 1 per cent osmium tetroxide in Ringer's solution adjusted to the osmolarity of frog plasma. The endolymphatic space was opened and some fixative was introduced. Immediately afterwards, the labyrinth was dissected and placed in the same osmium tetroxide solution and fixed for periods ranging from 30 minutes to 2 hours. The specimens were rinsed in Ringer's solution, dehydrated in ascending concentrations of alcohol and embedded in Epon as described by Luft (1956).

Thick sections were cut for survey purposes and stained with toluidine blue. Thin sections, cut with a LKB Ultrotome, were picked up on formvar-covered copper grids, stained with uranyl acetate and lead citrate (Reynolds, 1963) and examined in an Elmiskop I. Photographs were taken in the electron microscope at magnifications of from ×600 to ×40 000 and further magnified during the copying procedure. Gevaert Scientia plates and Gevaert paper were used.

Results

Physiological Observations

All the frogs in which one or more ampullar nerve branches had been divided and on which functional tests were performed showed signs of loss of function of the corresponding crista similar to those originally described by McNally & Tait (1925, 1933) and also by Gribenski (1963) and others. When only the nerve to the *horizontal* crista was cut, loss of function of the ipsilateral horizontal canal was first observed; about 1–2 weeks later the function of that canal seemed to reappear and over the next two weeks there was a progressive return to normal. In some of the animals in which one of the ampullar nerves had been transposed to the other crista there was the corresponding type of functional impairment of both cristae followed after 2–3 weeks by signs of paradoxical innervation of the crista (Gribenski's "reaction R"). Where the anterior vertical crista was innervated by the horizontal nerve there was thus a reaction indi-

Fig. 2. Survey of normal crista ampullaris with sensory cells, supporting cells and distal parts of the ampullar nerve which loses its myelin sheath close to the basement membrane.

cative of stimulation of the horizontal nerve when the vertical canal was stimulated. These signs of a paradoxical effect lasted for from a few days up to 2–3 weeks; there was then a steady recovery of normal function which was complete after a month or so. In a few animals there was no paradoxical response but a period of recovery of normal function similar to that found on simple section of the horizontal nerve.

Gross morphology of Vestibular Nerve after Transection

After fixation, the specimens were examined under a dissection microscope and further dissected in the Epon blocks. For a few days after simple division of one ampullar nerve there was a defect between the central and peripheral stumps owing to retraction of the latter. Three

cristae were isolated from the accompanying vessels and one or both nerves were divided depending on the type of experiment In one set of experiments the proximal stump was left in contact with the distal stump while in the other one of the proximal stumps was transposed to the distal stump of the other ampullar nerve. In order to increase the distance between the two stumps in the transposition experiments, the distal stump that should not reinnervate the crista was displaced and deflected proximally The mucosal flap was applied and sutured over the operation cavity

from the transposed reinnervating nerve. The relations between the two nerves and the cristae increasingly resembled those in the normal structure.

Fine Structural Changes in Sensory Cells and Nerve Endings during De- and Regeneration

Normal controls

The fine structure of the sensory epithelia in the controls was essentially identical with that of normal cristae. The structural organization of the hair cells and their synaptic areas has been described by Wersäll et al. (1967) and is illustrated here for comparison with the experimental material in Figs. 2–5.

Degenerative phase

The degenerative phase was taken to be the first 5 post-operative days during which there was no evident regeneration in the most distal part of the distal stump. No distinction was made between the nerves that were only divided

Fig. 3. Normal sensory cell with afferent and efferent nerve endings.

or four days later, however, the continuity between the peripheral and the central stumps was restored. The distal part of the nerve never completely lost its stainability with osmium. About 7–8 days after division fine fibres staining light brown appeared in the distal stump. They gradually increased in number and darkened until it was difficult to distinguish them from the normal nerve.

In those cases in which one of the branches was transposed from one ampulla to the other, reinnervation of the recently attached distal stump appeared at about the same time as after the simple division of the nerve. Some fibres also found their way from the reinnervated distal stump to the crista it originally innervated. Fibres also came from the original central stump of the ampullar nerve and mixed with those growing

Degenerative phase

The degenerative phase was taken to be first 5 post-operative days during which th was no evident regeneration in the most di part of the distal stump. No distinction was m between the nerves that were only divi

and those where a transposition was also performed

30 minutes (one animal). Already 30 minutes after transsection definite changes were observed in the distal stump of the nerve close to the site of the division (Fig. 6). The axons were oedematous, there was extensive disorganization of neurofibrils, the mitochondria showed evidence of degeneration and there was widespread splitting of the lamellae in the myelin sheaths. There were only minor changes in the unmyelinated part of the nerve fibres extending to the basement membrane, but some dark bodies without membrane structures were seen, and some vacuoles appeared in the axon (Fig. 7). The neurofibrils were mostly intact.

In the afferent nerve endings some of the vesicles had disintegrated between others there was oedema and other vesicles were clumped together. Even some of the mitochondria were slightly swollen with disintegration of the mitochondrial membrane (Fig. 8). The synaptic contact had not changed appreciably. The synaptic body was in normal contact with the plasma membrane on the presynaptic side in the hair cell, and was surrounded by synaptic vesicles. There appeared to be a decrease in the number of vesicles and in the size of coated vesicles and tubules surrounding the synaptic area. No other changes were found in the sensory cells themselves.

6 hours (one animal). 6 hours after the nerves had been divided the endings displayed marked changes (Fig. 9): these included oedematous swelling of the nerve endings, degeneration of mitochondria with swelling and disintegration of mitochondrial membranes, swelling and lack of contrast in the synaptic vesicles and disappearance of the dense part of vesicles that were of the dense type. The synaptic contact was intact and the synaptic bodies still maintained contact with the plasma membrane and were surrounded by synaptic vesicles.

The distal stump of the nerve branch showed signs of extensive disintegration (Fig. 10). The splitting of the myelin sheath and the degeneration of the axons had continued. Large dark bodies in the Schwann cells suggested that disintegration of some of the myelin had occurred. A few nerve fibres displayed remarkably little evidence of change.

18–20 hours (2 animals). After 18–20 hours, the unmyelinated part of the nerve fibres and the nerve endings exhibited severe degeneration. The mitochondria had lost most of their cristae. Some of them were swollen, while others were clumped together to form either irregular dense bodies surrounded by large vesicles, or large vacuoles (Fig. 11). Small filaments were observed in the nerve endings, whereas the number of vesicles was considerably reduced. The nerve endings had sometimes lost contact with the synaptic membranes or there was detachment of the nerve endings from the sensory cell, with wide spaces between them and defects in the plasma membrane of the nerve ending. Usually however there was still attachment at the site of the synaptic body. Synaptic bodies remained in the sensory cell surrounded by a few synaptic vesicles (Fig. 12).

Efferent nerve fibres were found in the sensory epithelium and although oedema had appeared in the nerve endings, synaptic vesicles and mitochondria with only minor changes remained numerous (Fig. 13). The efferent nerve endings were still in contact with the sensory cells and the subsynaptic sacs on the sensory cell side of the synapse were intact. The supporting cells contained large accumulations of dark bodies—presumably débris from degenerating nerve endings and fibres. Even in the sensory cells there

appeared to be some increase in the number of dark bodies, but otherwise these cells were intact with normal sensory hairs, mitochondria and other structures (Fig. 14).

24 hours (? animals). After 24 hours, there were areas in which no afferent nerve endings could be found. Opposing sensory cells were separated by globular spaces (Fig. 15) some of these were located where the nerve endings had disappeared as indicated by synaptic bodies still surrounded by synaptic vesicles (Fig. 16) The efferent nerve endings appeared to be quite normal (Fig. 17) In one of the specimens there were no changes in the sensory and supporting cells other than those in the animals described above, while in the other several sensory cells were severely changed with marked swelling of the nuclei and the cytoplasm filled with vacuoles and multi vesicular bodies. Other sensory cells were apparently normal, although a few showed a shrinkage of the cytoplasm with high electron density which was still more intense in the nuclei. The supporting cells and the above-mentioned relationships between nerve endings and cells were the same as in the first specimen at the same stage The differences described might have been due to a change in the preparatory technique at a critical stage which is further discussed below

2 and 3 days (3 animals) In specimens taken 2 and 3 days after transsection there was evidence of progressive degeneration of afferent nerve fibres, terminal branches and nerve endings. Schwann cells in the distal stump of the nerve showed signs of phagocytotic activity with numerous inclusions (Fig. 18) In contrast the part of the nerve proximal to the lesion contained normal axons, myelin sheaths and Schwann cells (Fig. 19) Some fibres in the distal stump were better preserved than the others Most of the afferent nerve endings were disintegrated, those remaining being severely changed (Fig. 20). Efferent nerve fibres were still in contact with sensory cells, but at this stage vesicles were disintegrating and being replaced by a granular filamentous substance Even the mitochondria displayed evidence of degeneration. In places the subsynaptic sac showed a tendency to break up but this specific structure was highly irregular in shape even in the normal material (Fig. 21). The surface and the hairs of the sensory cells were usually intact but there was some increase in the amount of foreign material in the cell bodies. The supporting cells contained more definite accumulations of inclusion bodies. Even when the nerve endings had completely disappeared, there were still many synaptic bodies near the plasma membrane and these were surrounded by a few synaptic bodies.

5 and 6 days (2 animals). After simple transsection of ampullar nerves, some hair cells had very large irregular sensory hairs and protrusions of parts of the cuticle, although the configuration of the mitochondria ribosomes and cytoplasm in general was normal and the cells still had several intact synaptic bodies.

7 days (one animal) The sensory and supporting cells were essentially the same as those in the 2–3-day material without the changes in the cuticula and sensory hairs.

8 days (one animal) The cells in the crista had also a rather normal appearance in this specimen, but some accumulations of fine granular

13 days (one animal). When the horizontal ampullar nerve had been divided and transposed to the distal stump of the anterior vertical nerve, the horizontal crista had intact sensory cells with a normal surface, sensory hairs and kinocilia (Fig. 23). The sensory cells were apparently devoid of nerve endings in all sections and no nerve reached this crista. Some synaptic bodies were still attached to the plasma membrane: they were surrounded by a single layer of synaptic vesicles and often located in an area in which the sensory cells were in contact with supporting cells (Fig. 24). Thus, the open spaces formed by the degenerating nerve endings had disappeared at this stage.

Most of the foreign material accumulated in supporting sensory cells had also disappeared. To judge from the general appearance of the sensory epithelium, its reaction was less pronounced than a few days previously and it seemed that a certain amount of recovery had taken place.

In the anterior vertical crista, which was supplied by the branch from the horizontal nerve, a large number of regenerating nerve fibres were seen (Fig. 25). They reached the sensory cells and new nerve endings were found in contact with the synaptic area of the sensory cells, however no complete synaptic structure could be identified (Fig. 26). In the majority of these nerve endings there was a very dense accumulation of mitochondria and sparse vesicles. No efferent fibres were identified.

15 days (one animal). After division of both ampullar nerves close to the bifurcation, nerve fibres were found below the epithelia but not inside them. In some sensory cells in the anterior

Fig. 28 Part of reinnervated crista with sensory and supporting cells of normal appearance (4. d post-op.).

material and the presence of a few cells with amoeboid protrusions in the endolymphatic space suggested an inflammatory reaction (there was also an increased amount of osmium-stained material in the perilymphatic linings seen at dissection)

Regenerative phase

A few regenerating nerve fibres were found in the basal part of the epithelium only *7 days* after transsection without transposition of the nerve (Fig. 22)

The sensory cells were apparently devoid of nerve endings in all sections and no nerve reached this crista. Some synaptic bodies were still attached to the plasma membrane: they were surrounded by a single layer of synaptic vesicles and often located in an area in which the sensory cells were in contact with supporting cells (Fig. 24). Thus, the open spaces formed by the degenerating nerve endings had disappeared at this stage.

Most of the foreign material accumulated in supporting sensory cells had also disappeared. To judge from the general appearance of the sensory epithelium, its reaction was less pronounced than a few days previously and it seemed that a certain amount of recovery had taken place.

In the anterior vertical crista, which was supplied by the branch from the horizontal nerve, a large number of regenerating nerve fibres were seen (Fig. 25). They reached the sensory cells and new nerve endings were found in contact with the synaptic area of the sensory cells; however, no complete synaptic structure could be identified (Fig. 26). In the majority of these nerve endings there was a very dense accumulation of mitochondria and sparse vesicles. No efferent fibres were identified.

15 days (one animal). After division of both ampullar nerves close to the bifurcation, nerve fibres were found below the epithelia but not inside them. In some sensory cells in the anterior

material and the presence of a few cells with amoeboid protrusions in the endolymphatic space suggested an inflammatory reaction (there was also an increased amount of osmium stained material in the perilymphatic linings seen at dissection).

Regenerative phase

A few regenerating nerve fibres were found in the basal part of the epithelium only *7 days* after transsection without transposition of the nerve (Fig. 22).

Fig. 29. Survey of basal part of crista with nerve terminals in contact with sensory cells (42 d post-op.).

Figs. 30–31. Two sections of an afferent nerve ending in synaptic contact with sensory cell. Note the accumulation of mitochondria in the ending and the large number of vesicles around the synaptic body (42 d post-op.).

13 days (one animal). When the horizontal ampullar nerve had been divided and transposed to the distal stump of the anterior vertical nerve, the horizontal crista had intact sensory cells with a normal surface, sensory hairs and kinocilia (Fig. 23). The sensory cells were apparently devoid of nerve endings in all sections and no nerve reached this crista. Some synaptic bodies were still attached to the plasma membrane; they were surrounded by a single layer of synaptic vesicles and often located in an area in which the sensory cells were in contact with supporting cells (Fig. 24). Thus, the open spaces formed by the degenerating nerve endings had disappeared at this stage.

Most of the foreign material accumulated in supporting sensory cells had also disappeared. To judge from the general appearance of the sensory epithelium, its reaction was less pronounced than a few days previously and it seemed that a certain amount of recovery had taken place.

In the anterior vertical crista, which was supplied by the branch from the horizontal nerve, a large number of regenerating nerve fibres were seen (Fig. 25). They reached the sensory cells and new nerve endings were found in contact with the synaptic area of the sensory cells, however, no complete synaptic structure could be identified (Fig. 26). In the majority of these nerve endings there was a very dense accumulation of mitochondria and sparse vesicles. No efferent fibres were identified.

15 days (one animal). After division of both ampullar nerves close to the bifurcation, nerve fibres were found below the epithelia but not inside them. In some sensory cells in the anterior

Fig. 3. Efferent nerve ending in synaptic contact with a sensory cell. The synaptic complex is normally differentiated (4 d post-op.).

crista cytoplasm was rather poorly structured with an increase in the number of small vacuoles, but the cells, including the synaptic bodies, were otherwise normal as described above. In the horizontal crista the cells had a normal structure.

20 days (one animal). The distal part of the nerve contained a mixture of a few apparently normal myelinated fibres, large numbers of unmyelinated nerve fibres, accumulations of degenerated myelin sheaths, and Schwann cells filled with degenerated material. The sensory epithelium was richly supplied with branching nerve terminals although some synaptic bodies still remained in contact with areas where sensory cells were attached directly to a supporting cell. Other synaptic bodies were found in the synaptic areas of newly formed nerve endings. From this stage on more or less complete afferent complexes were observed (Fig. 27). The nerve terminal now contained mitochondria of varying sizes, and vesicles, some of which were seen to have dense central cores.

28 days (one animal). The picture was essentially similar to the preceding specimen, while at *37 days (one animal)* one efferent nerve ending was found in synaptic contact with a sensory cell. In the latter specimen there were also a great many nerve fibres in various initial stages of myelinization, intermingled with bundles of unmyelinated fibres in the terminal parts of the regenerated nerve.

42 days (one animal). The electron microscopic survey of the reinnervated crista showed normal sensory cells (Fig. 28). The appearance and orientation of the sensory hair bundles were as in the normal frog. There were a large number of terminal nerve fibres between the basal parts of the cells of the crista (Fig. 29). The synaptic structure of afferent nerve endings in contact with the sensory cells was normal (Figs. 30, 31) and efferent nerve endings with a large accumulation of synaptic vesicles were found in the epithelium (Fig. 32). Besides the vesicles, the afferent nerve endings contained numerous mitochondria and some dense bodies. The contact between the afferent ending and the sensory cell was well established and the various structures of the synapse had formed. Some of the synaptic bodies were surrounded by large numbers of synaptic vesicles. Thus, although nerve fibres were still fewer than in the control material, those that had reached the epithelium had established normal morphological contact with the

sensory cells. The specimen fixed and prepared after 46 days was at essentially the same stage as that from the 42-day animal, however the poorer preservation of fine structure in the specimen precluded more detailed analyses.

Discussion

Object of Study and Methodological Problems

In the present study attention was focused on the structural relation between the nerve terminals and sensory cells during the interval between the division of the ampullar nerve and the restoration of functional and morphological organization.

The technical approach was limited to the part of the labyrinth containing the two rostral ampullar nerves and the related cristae. This afforded the possibility of selective elimination of the nervous supply to one crista, while the other could be used as a control—an advantage because of the variations in tissue fixation. In animals in which both ampullar nerves were divided and in most of the others, the controls were the posterior crista of the ipsilateral labyrinth and one or more of the contralateral cristae.

Even simple transection of the nerve may lead to damage (for instance anoxia, infection or toxic metabolites may result in changes in different parts of the specimen. In a few cases, division of major vessels was followed by rapid disintegration of the nerves and the sensory epithelia, but in most of the surviving animals the circulation was acceptable. When the division was performed distally to the common branch of the nerve there was minimal disturbance of the visible arterial capillaries along the nerve. In a few specimens, the nerve was cut further proximally but, because of microscopic evidence of a deterioration of the circulation, this method was abandoned.

During the preparation of the specimens for ultrastructural study there is also great danger of mechanical traumatization which may produce changes at the cellular level if the fixative has not penetrated the tissues adequately. In some cases, attempts were made to dissect the labyrinths carefully before fixation and place the anterior part of them in a fixative. On subsequent electron microscopy the same type of changes as described for one of the 24 h-specimens were found—some sensory cells had intensely swollen nuclei and vacuolization of the cytoplasm, others were normal or shrunken (and the tops of some cells were also ruptured, allowing extrusion of cytoplasmatic components into the endolympatic space). In fact, this particular specimen (and two others in the series) was dissected a little more brusquely than the others—the bony capsule was opened by means of a watchmaker's forceps instead of by drilling.

One aim of the present investigation was to examine the results of false innervation by transposing one nerve to the neighbouring crista. In the restricted area close to the crista where the nerve was divided the nerves were so short that the time for complete outgrowth was only about 2 weeks, thus, no examination of denervated epithelium over a longer period could be made in this study.

Gross Regeneration of Nerve Fibres

For comparison with the gross morphological pictures reported by Gribenski (1963), an attempt was made to follow the course of degeneration and regeneration of the nerves by inspecting the specimens in vivo and during the fixation and staining procedures. One essential difference between the methods is that whereas Gribenski destroyed the horizontal crista by cauterization in order to eliminate nerve contacts and impulses from the crista, in the present study an attempt was made to minimize the lesions so as to pre-

serve the normal ultrastructure. The regenerating fibres were seen to grow centrifugally from the two proximal nerve stumps and in a short time there was intermingling of their fibres. About 2 weeks postoperatively there was clear reinnervation of the vertical crista from the horizontal nerve. At the same time tests revealed a physiological response similar to Gribenski's "reaction R" thus corresponding in time with his findings. The regenerated fibres subsequently reached the two cristae from the horizontal nerve stump and fibres from the anterior nerve grew into the anterior crista. It was not clear whether the anterior nerve also contributed to the innervation of the horizontal crista.

Degeneration of Nerve Fibres and Terminals

The changes in axons and myelin sheaths after sectioning of the nerves do not differ from the pattern described by other workers (e.g. Glimstedt & Wohlfahrt 1960, Ohmu, 1962). However the myelin alterations seem to be comparatively rapid, probably due to the small distance between the lesions and the nerve terminals. No regular changes were found in the proximal stumps, other than in the immediate vicinity of the lesions, but signs of retrograde degeneration were not systematically looked for. The pattern of degeneration in the nerve terminals has received considerably more attention in the literature, especially in connection with the experiments on selective destruction in the central nervous system, where identification of the degenerating fibres in based on changes interpreted as evidence of degeneration.

Three types of anterograde degenerative changes in nerve endings in the central nervous system have been described. The first is characterized by a striking initial increase in the number of neurofilaments, accompanied by swelling of the damaged process and followed by shrinkage of the profile and considerable increase in electron density. The second type consists of an increase in the electron density of the axoplasm with no loss of synaptic vesicles and little alteration in the size and shape of the terminal. The third type has been referred to as electron-lucent or "pale" degeneration due to its lack of axoplasmic electron-density and apparent loss of synaptic vesicles (Raisman & Matthews, 1972, O'Neal & Westrum 1973, Gentschev & Sotelo, 1973). The interrelationships between these types of degenerative change do not seem to be quite clear and there are variations according to the species studied, the age of the animal and the system chosen for study. The heterogeneity of degenerative patterns is greater in the peripheral nervous system than in the CNS and the reaction of the terminals in peripheral sites is more rapid than in the central ones (Raisman & Matthews 1972). Apparently there are also variations between different specimens due to variations in the preparative and fixative procedures used. The main problem in the present study was not to separate undegenerated terminals and terminals of similar type in various stages of degeneration in order to trace a distinct tract, but to follow the changes in time in a limited series of animals. The asynchronism of degeneration may result in disappearance of many terminals while others of an identical type may appear to be little changed. Hillman (1969) showed that all efferent nerve endings in the labyrinth of the frog do not degenerate at the same rate.

Two days after dividing the crossed olivo-cochlear bundle in guinea pig, Kimura & Wersäll (1962) found alterations in the large efferent endings of the cochlea, with an increase in the density of the synaptic vesicles in the terminals, followed by degeneration of mitochondria and complete degeneration of the nerve endings 5 days after division. Transsection of the cochlear nerve in the internal auditory meatus led to degeneration of the efferent and more slowly of the afferent nerve endings. The later degeneration of the afferent terminals was ascribed to a survival of the ganglion cells for a time after division of the nerve. Iurato (1962) reported changes in the efferent endings in the rat as early as 16 hours after sectioning of the olivo-cochlear bundle. Smith & Rasmussen (1963) showed regressive changes in the large nerve endings on the outer hair cells in the

cochlea of the chincilla 3 days after cutting the olivo-cochlear bundle. Débris of the endings were found after as much as 32 days. The same authors reported (1968) degeneration of efferent nerve endings in the vestibule 6–8 days after dividing the efferent nerve bundles in the medulla. After sectioning the olivo-cochlear bundle in the internal acoustic meatus, Spoendlin (1966) found distinct signs of degeneration of the large vesiculated endings in cat after one week. He has later (1971) shown that the apparent persistence of innervation in the organ of Corti after sectioning the cochlear nerve is to be ascribed to the survival of a small number of cells in the spiral ganglion, which send their axons to both the outer and the inner hair cells and which resist retrograde degeneration. Remarkably rapid degeneration of the efferent nerve endings was found by Hillman (1969) after cutting the vestibular nerve and brain stem in frog. He presented pictures of dense masses formed from degenerated efferent nerve endings within 2 days after the lesion. This type of change was not found in the present material where rather well preserved endings were found even after 3 days. It is, however, obvious that a large number of nerve endings had disappeared at this stage. Hillman also noted that many of the efferent fibres were lost already after 2 days. This should be compared with the report by Robbins et al. (1967) that a rather small number of efferent fibres was found in the nerve branches to the sensory epithelia 2–3 weeks after cutting the vestibular nerve.

In the present material the marked changes in the distal stump of the nerve and in the afferent endings shortly after division may be due to an increase in the permeability of capillaries in the nerve, as was shown in peripheral nerves by Mellick & Cavanagh (1968) and also discussed by Berger (1971). During the next 24–48 hours there was progressive degeneration. In contrast to these consistent changes in the afferent nerve endings, there was no sign of changes in the efferent endings after 2 days. On the third day disintegration of the vesicles was evident. This difference in the time course of the degenerative changes in the efferent and afferent nerve endings in a particular end organ specimen may be due to a higher rate of metabolism in the afferent nerves and nerve endings than in the efferent ones. In the specimens there are no efferent action potentials in the distal stump, and no transmission in the efferent synapses, which implies a reduction in the consumption of energy. The transmission in the afferent synapses and nerves is essentially unchanged (Gleisner & Henriksson, 1964) or possibly increased owing to loss of the inhibitory effect of the efferents, as was shown in frog by Llinás & Precht (1969) and by Goetmakers & Groen (1970). Thus, the metabolic demand is not reduced in afferents and when energy-rich substrates cannot be supplied from the cell body by normal axonal proximo-distal transport this may lead to a more rapid degeneration than in the efferents. This explanation might imply that some substances are involved in the maintenance of both structural and functional integrity and may be related to the fast component of transport in axons, shown by Ochs (1972) to utilize ATP and also thought to be responsible for supplying materials specifically required at the synaptic terminals (Grafstein, 1969).

Regenerating Nerve Fibres

During the regenerative phase, afferent nerve endings were found long before efferent ones. This may be due to the fact that the distance between the efferent nerve cell-body and the end organ is greater than that between the afferent nerve cell-body and the end organ, provided that the growing tip of the proximal stump is dependent on newly synthesized materials carried from the cell body by means of the slow component of axoplasmic transport.

The fact that those parts of the synapses which belonged to the hair cell (synaptic body, vesicles, end-foot and membrane) were often intact during the denervated stage suggests that the synapses in regenerated specimens are really original synaptic points. The possibility that de novo contacts develop between nerve endings

serve the normal ultrastructure. The regenerating fibres were seen to grow centrifugally from the two proximal nerve stumps, and in a short time there was intermingling of their fibres. About 2 weeks postoperatively there was clear reinnervation of the vertical crista from the horizontal nerve. At the same time tests revealed a physiological response similar to Gribenski's "reaction R" thus corresponding in time with his findings. The regenerated fibres subsequently reached the two cristae from the horizontal nerve stump and fibres from the anterior nerve grew into the anterior crista. It was not clear whether the anterior nerve also contributed to the innervation of the horizontal crista.

Degeneration of Nerve Fibres and Terminals

The changes in axons and myelin sheaths after sectioning of the nerves do not differ from the pattern described by other workers (e.g. Glimstedt & Wohlfahrt, 1960; Ohm, 1962). However the myelin alterations seem to be comparatively rapid, probably due to the small distance between the lesions and the nerve terminals. Regenerating Nerve Fibres

During the regenerative phase, afferent nerve endings were found long before efferent ones. This may be due to the fact that the distance between the efferent nerve cell-body and the end organ is greater than that between the afferent nerve cell-body and the end organ, provided that the growing tip of the proximal stump is dependent on newly synthesized materials carried from the cell body by means of the slow component of axoplasmic transport.

The fact that those parts of the synapses which belonged to the hair cell (synaptic body, vesicles, end-foot and membrane) were often intact during the denervated stage suggests that the synapses in regenerated specimens are really original synaptic points. The possibility that "de novo" contacts develop between nerve endings

serve the normal ultrastructure. The regenerating fibres were seen to grow centrifugally from the two proximal nerve stumps and in a short time there was intermingling of their fibres. About 2 weeks postoperatively there was clear reinnervation of the vertical crista from the horizontal nerve. At the same time tests revealed a physiological response similar to Gribenski's "reaction R", thus corresponding in time with his findings. The regenerated fibres subsequently reached the two cristae from the horizontal nerve stump and fibres from the anterior nerve grew into the anterior crista. It was not clear whether the anterior nerve also contributed to the innervation of the horizontal crista.

Degeneration of Nerve Fibres and Terminals

The changes in axons and myelin sheaths after sectioning of the nerves do not differ from the pattern described by other workers (e.g. Glimstedt & Wohlfahrt 1960, Ohmi 1962). However the myelin alterations seem to be comparatively rapid, probably due to the small distance between the lesions and the nerve terminals. No regular changes were found in the proximal stumps, other than in the immediate vicinity of the lesions, but signs of retrograde degeneration were not systematically looked for. The pattern of degeneration in the nerve terminals has received considerably more attention in the literature, especially in connection with the experiments on selective destruction in the central nervous system, where identification of the degenerating fibres is based on changes interpreted as evidence of degeneration.

Three types of anterograde degenerative changes in nerve endings in the central nervous system have been described. The first is characterized by a striking initial increase in the number of neurofilaments, accompanied by swelling of the damaged process and followed by shrinkage of the profile and considerable increase in electron density. The second type consists of an increase in the electron density of the axoplasm with no loss of synaptic vesicles and little alteration in the size and shape of the terminal. The third type has been referred to as electron-lucent or "pale" degeneration due to its lack of axoplasmic electron-density and apparent loss of synaptic vesicles (Raisman & Matthews, 1972, O'Neal & Westrum, 1973, Gentschev & Sotelo, 1973). The interrelationships between these types of degenerative change do not seem to be quite clear and there are variations according to the species studied, the age of the animal and the system chosen for study. The heterogeneity of degenerative patterns is greater in the peripheral nervous system than in the CNS and the reaction of the terminals in peripheral sites is more rapid than in the central ones (Raisman & Matthews 1972). Apparently there are also variations between different specimens due to variations in the preparative and fixative procedures used. The main problem in the present study was not to separate undegenerated terminals and terminals of similar type in various stages of degeneration in order to trace a distinct tract, but to follow the changes in time in a limited series of animals. The asynchronism of degeneration may result in disappearance of many terminals while others of an identical type may appear to be little changed. Hillman (1969) showed that all efferent nerve endings in the labyrinth of the frog do not degenerate at the same rate.

Two days after dividing the crossed olivo-cochlear bundle in guinea pig, Kimura & Wersäll (1962) found alterations in the large efferent endings of the cochlea, with an increase in the density of the synaptic vesicles in the terminals, followed by degeneration of mitochondria and complete degeneration of the nerve endings 5 days after division. Transsection of the cochlear nerve in the internal auditory meatus led to degeneration of the efferent and, more slowly, of the afferent nerve endings. The later degeneration of the afferent terminals was ascribed to a survival of the ganglion cells for a time after division of the nerve. Iurato (1962) reported changes in the efferent endings in the rat as early as 16 hours after sectioning of the olivo-cochlear bundle. Smith & Rasmussen (1963) showed regressive changes in the large nerve endings on the outer hair cells in the

with signs of degeneration or derangement of the morphological polarization after denervation. In the case of some other secondary organs, degenerative processes which proceed differently have been described in the receptor cells. Thus, in fishes and mammals, taste buds gradually degenerate and disappear in a relatively short time after denervation, often within 1–2 weeks (reviews by e.g. Zelená, 1964; Jeppson, 1969). An exceptionally slow degeneration of taste cells in the frog was noted by Robbins (1967); this has been related to the special morphological characteristics of the cells in that species (Guth, 1971). Lateral-line organ sensory cells degenerate rapidly in fish but after varying periods of time in amphibia where, according to Jones & Singer (1969), the first changes in the adult newt appear within 3 weeks after elimination of both the lateral-line and the spinal nerves, leading to advanced degeneration within 2 months. However the earlier much debated, but generally accepted, theory of a dependence of sensory cells on nervous connections in terms of a trophic influence, leading to total elimination of the cells after a prolonged period of nerve deprivation seems, in certain respects to be contradicted by the findings of Flock et al. (1973). They observed autonomous differentiation and normal morphological polarization of hair cells of salamander tadpoles devoid of innervating nerve endings. Certain specialized lateral-line organs, namely electroreceptors, such as the tuberous organ of mormyrid fish, degenerate in 2–12 days after denervation (Roth & Szabo, 1969), and rapid changes have been described in the sensory cells of the ampullary organ of catfish (Szamier & Bennet, 1973) and the ampullae of Lorenzini of electric ray (Derbin, 1970) where the presynaptic rods are changed within 6–12 hours and 3–4 days respectively after nerve section; signs of cytoplasmatic degeneration appearing later in these cells.

The persistence of the sensory cells in the organ of Corti after sectioning of the cochlear nerve, as reported by Spoendlin & Gacek (1963) and others is probably not a conclusive sign that hair cells are independent of nervous contacts, as nerve terminals have been found in the organ; such endings probably belong to surviving cells in the spiral ganglion (Spoendlin, 1971).

Vestibular sensory cells have been reported to degenerate after cutting the ampullar nerves in squirrel monkeys (Igarashi & Miyata, 1972), but similar results in cats were interpreted by Mair & Fernández (1966) as being caused by nervous ischemia; this was corroborated by Silverstein & Makimoto (1973) who found no light microscopical signs of vestibular cell degeneration in cat when the vessels were intact at nerve sectioning. Gribenski (1963) showed advanced degeneration of the ampullar crista in the frog 4 weeks after nerve division, provided regeneration was prevented ("e.g. by destruction of the ganglion of Scarpa"), but the degree of vascular interference in those preparations was not described. Our pilot experiments in which the nerve was cut proximal to the utricular branch resulted in an obvious decrease in the peripheral circulation, and in rapid degeneration in the sensory epithelia. Following careful peripheral cutting as described above, we found only *rare examples of* sensory cell alterations, no evidence of total cell degeneration and no signs of breaking of the presynaptic afferent complex in a denervated stage. However it is quite possible that a more pronounced degeneration would have taken place if the epithelium had been deprived of nervous connections for longer periods than 1–2 weeks.

At the denervated stage, efferent postsynaptic structures could not be identified in the hair cells. Elongated spaces with a limiting membrane could be seen in the basal parts in the proximity of the sensory cell wall, but such structures, without relations to nerve endings were also sometimes found in normal sensory cells. Thus, it was not possible to exclude some loss of structural integrity of the efferent postsynaptic sites, as was shown by Kimura & Wersäll (1962) in the organ of Corti of the guinea pig. In the sympathetic ganglion cells of the frog there are however no signs of transsynaptic changes after denervation (Sotelo, 1968). There are also many examples of persistence of postsynaptic speciali-

and cells during the regenerative phase cannot however be ruled out

When hair cells in the lateral line canal organ of salamander tadpoles are studied *in vivo* synaptic bodies can be seen to change their positions, and during differentiation of epithelial cells into hair cells in denervated preparations synaptic bodies are found freely distributed in the cytoplasm (Flock et al 1973) This might imply a plasticity of afferent presynaptic sites also in developed hair cells during denervated stages which is however difficult to see in ordinary sections The existence of synaptic bodies surrounded by vesicles without close contact with the cell membrane has, however in some instances been confirmed by us in operated animals studied by serial sectioning.

The marked specificity in a regenerating nerve fibre to reestablish contact with the end organ or neuron to which it was originally connected, has been ascribed to specific biochemical characteristics of the neuron, which are determined by developmental processes early in differentiation Examples of the reestablishment of specific connections are provided by retinal cells and the optic tectum (Sperry 1963 Jacobsson 1968) It is, however possible for a nerve to make contact with another neuron or another end organ, within certain limits (sensory nerves do not form functional connections with muscles, and motor nerves do not innervate sensory organs) The new inappropriate contact is then promoted if not actually made possible by denervation of the organ to be contacted (Sperry & Arora 1965) This was also observed when the horizontal ampullar nerve reinnervated the anterior crista in the frog, producing synaptic structures of normal appearance but with a tendency for misdirection of vestibular reflexes

At a later stage fibres from the same nerve grew further to the horizontal crista. The 'false innervation stage' was possible only a transitory phase before there was complete reorganization of the original contacts, as no obstacle to this process was provided (cf Sperry 1945) On the basis of the present material it has not been possible to establish whether or not the transposed fibres from the horizontal nerve remain in contact with the sensory cells of the anterior crista. However no degenerating nerve endings were found in the sensory epithelia which were reinnervated by any of the nerves. An interesting observation was made by Marotte & Mark (1970*a* *b*) and Mark et al. (1972) who noted persistence of ultrastructurally normal synaptic endings on the eye muscles of fish after cross unions of oculomotor nerves, which first resulted in movements controlled by the newly (inappropriate) innervating nerves, but after regeneration of the proper nerves the muscles regained their normal functions apparently the synaptic functions of the improper nerve endings had been blocked or the muscles had been insensitive to transmitter when their original nervous contacts had been reestablished No signs of degeneration of the endings which arrived first could be found The result point to the possibility that selective mechanisms are involved in the developmental patterning of synaptic connections and that they also influence the efficiency of transmission at formed synaptic complexes.

There is strong evidence that specificity of peripheral sensory and motor neurons is mediated from their peripheral connections In early developmental stages the central synaptic associations are specified by means of biochemical mechanisms. In these early stages it seems to be possible to change central connections, as in the case of respecification of cutaneous nerves after transplanting skin from the back to the belly of frog tadpoles, resulting in misdirected reflexes after metamorphosis, (Jacobson & Baker 1969). Whether central synaptic reorganization is possible later in ontogeny or in higher animals is less certain only few indications of such a plasticity have been reported (see Jacobsson 1971 Cragg, 1972)

Sensory Cells after Denervation

One aim of the present experiments was to find out whether the sensory cells of the crista reacted

Concluding Remarks

On the basis of the observations made in this study it would appear that sensory cells in the labyrinth survive total denervation for a short period without regular signs of ultrastructural damage. Moreover afferent synaptic structures in these cells are often preserved in the denervated stage, and afferent and efferent nerves reinnervate the vestibular epithelium after division of the ampullar nerve. The afferent nerves degenerate and regenerate earlier than the efferent ones. The nerve fibres from horizontal ampullar nerves can innervate a denervated anterior vertical crista, but this results in misdirected reflexes. The initiation of morphological and functional normalization becomes evident about one month after division of the nerve.

Summary

The degeneration and regeneration of afferent and efferent nerves to the crista ampullaris in the frog were studied after transection of the ampullar nerves. In some experiments one or both rostral ampullar nerves were simply divided and left in place. In other experiments the ampullar nerves to the horizontal and to the anterior vertical crista were divided and the branch to the former was brought into contact with the distal stump of the anterior vertical ampullar nerve.

Sensory cells in the labyrinth survived total denervation for 1–2 weeks without regular signs of ultrastructural damage. The afferent synaptic structures in these cells were often preserved in the denervated stage. The afferent nerve fibres degenerated earlier than the efferent ones. Both type of fibres reinnervated the vestibular epithelium after division of the ampullar nerve. The fibres from a horizontal ampullar nerve could reinnervate a denervated anterior vertical crista, resulting in misdirected reflexes. About 40 days after division both function and morphological organization had been restored to normal.

Zusammenfassung

Entartung und Regeneration afferenter und efferenter Nerven der Crista ampullaris beim Frosch wurden nach Durchtrennung der Ampullennerven untersucht. Bei einigen Versuchen wurden einer oder beide rostrale Ampullennerven einfach durchtrennt und dabei gelassen. Bei anderen Experimenten wurden die Ampullennerven der horizontalen Crista wie auch der Crista anterior durchtrennt und danach der Ast der horizontalen Crista mit dem distalen Stumpf des N. ampullaris anterior anastomosiert.

Es wurde beobachtet, dass die Sinneszellen des Labyrinthes bei totaler Denervation ohne regelmässige Zeichen einer ultrastrukturellen Schädigung 1–2 Wochen überleben können. Die afferenten synaptischen Strukturen in diesen Zellen bleiben auch im Stadium der Denervierung oft erhalten. Die afferenten Nervenfasern degenerieren früher als die efferenten. Die afferenten wie auch die efferenten Nervenfasern besorgen die Reinnervation des vestibulären Epithels nach Durchtrennung der Ampullennerven. Die Nervenfasern eines horizontalen Ampullen-

zations after deafferentiation in the central nervous system they were often apposed by various elements (Pinching, 1969 O'Neal & Westrum 1973)

Relation between Morphology and Physiology

The misdirected vestibular reflexes elicited by impulses from the anterior crista to the horizontal nerve have been described by Gribenski (1963) who discussed the possibility of two types of nerve fibres in each ampullar nerve, one which takes part mainly in the tonic function of the labyrinth and another which participates especially during the stimulation produced by the flow of endolymph. Electrophysiological studies using single fibre recordings have shown that there are two principal groups of afferent fibre activity from the horizontal ampulla of the frog a small proportion show little or no adaptation on prolonged acceleration and are characterized by a rather regular resting activity while most fibres show a marked adaptation on stimulation and irregular frequency at rest. However all fibres in the horizontal nerve show an increase in frequency on utriculopetal deviations of the cupula (Flock & Gleisner 1968 cf. Precht et al. 1971 Goldberg & Fernandez, 1971*a b*) The so-called tonic function of the ampulla should rather be discussed in terms of the mere existence of nervous activity which gives a balanced input to the central connections in the animal from both labyrinths under resting conditions. The fact that an inappropriately reinnervated anterior vertical crista preserves its original morphological polarization after establishment of ultrastructurally qualitatively normal synaptic contacts of the afferent type implies that an increase in afferent nervous activity occurs on utriculofugal cupula deviation in the ampulla. The presence of misdirected reflexes is in good accordance with the view that the central connections do not change within the time of reinnervation. The initial phase of normalization of responses to tilting and rotatory stimuli after about 3–4 weeks in our material might be ascribed to the structural peripheral reorganization towards normal conditions as already discussed. There is also the possibility that after regeneration of efferent terminals an increased degree of efferent feedback contributes to an inhibition of inappropriate input at a stage when this peripheral reorganization has not taken place. Electrophysiological correlations of the behavioural responses and the morphological findings in the present type of experiment on the vestibular apparatus are not known to the authors. Furthermore the improvement of vestibular reflexes after peripheral lesions is known to be due to compensation at the level of the vestibular nuclei after partial or complete loss of normal input of nerve impulses from the labyrinth as has been shown by Precht et al. (1969) and McCabe et al. (1972). Gribenski noted that the frogs which exhibited a reaction "R" had a reduced response to horizontal rotatory stimuli compared with animals simply deprived of one horizontal crista about one month after the respective operations. A possible clue to the explanation of this result is the finding by Caston & Gribenski (1972) that the activity in most fibres of the intact anterior vertical ampullar nerve decreased on rotatory acceleration in the horizontal plane which causes increased activity in the horizontal nerve of the same side. This would give a simultaneous increase (or decrease) in the two horizontal nerves on testing the "R" frogs, resulting in a diminution of the differential input to the nuclei. Since we did not perform any quantitative measurements of those responses we were unable to confirm this finding.

Concluding Remarks

On the basis of the observations made in this study it would appear that sensory cells in the labyrinth survive total denervation for a short period without regular signs of ultrastructural damage. Moreover afferent synaptic structures in these cells are often preserved in the denervated stage, and afferent and efferent nerves reinnervate the vestibular epithelium after division of the ampullar nerve. The afferent nerves degenerate and regenerate earlier than the efferent ones. The nerve fibres from horizontal ampullar nerves can innervate a denervated anterior vertical crista, but this results in misdirected reflexes. The initiation of morphological and functional normalization becomes evident about one month after division of the nerve.

Summary

The degeneration and regeneration of afferent and efferent nerves to the crista ampullaris in the *frog* were studied after transsection of the ampullar nerves. In some experiments one or both rostral ampullar nerves were simply divided and left in place. In other experiments the ampullar nerves to the horizontal and to the anterior vertical crista were divided and the branch to the *former* was brought into contact with the distal stump of the anterior vertical ampullar nerve.

Sensory cells in the labyrinth survived total denervation for 1–2 weeks without regular signs of ultrastructural damage. The afferent synaptic structures in these cells were often preserved in the denervated stage. The afferent nerve fibres degenerated earlier than the efferent ones. Both type of fibres reinnervated the vestibular epithelium after division of the ampullar nerve. The fibres from a horizontal ampullar nerve could reinnervate a denervated anterior vertical crista, resulting in misdirected reflexes. About 40 days after division both function and morphological organization had been restored to normal.

Zusammenfassung

Entartung und Regeneration afferenter und efferenter Nerven der Crista ampullaris beim Frosch wurden nach Durchtrennung der Ampullennerven untersucht. Bei einigen Versuchen wurden einer oder beide rostrale Ampullennerven einfach durchtrennt und daliegen gelassen. Bei anderen Experimenten wurden die Ampullennerven der horizontalen Crista wie auch der Crista anterior durchtrennt und danach der Ast der horizontalen Crista mit dem distalen Stumpf des N. ampullaris anterior anastomosiert.

Es wurde beobachtet, dass die Sinneszellen des Labyrinthes bei totaler Denervation ohne regelmässige Zeichen einer ultrastrukturellen Schädigung 1–2 Wochen überleben können. Die afferenten synaptischen Strukturen in diesen Zellen bleiben auch im Stadium der Denervierung oft erhalten. Die afferenten Nervenfasern degenerieren früher als die efferenten. Die afferenten wie auch die efferenten Nervenfasern besorgen die Reinnervation des vestibulären Epithels nach Durchtrennung des Ampullennerven. Die Nervenfasern eines horizontalen Ampullen-

nerven können eine Crista anterior innervieren die denerviert wurde und funktionelle Fehlreaktionen verursacht. Morphologisch wie auch funktionell ist zirka 40 Tage nach dem Eingriff völlige Normalisierung erreicht.

CONTENTS

Introduction

On November 9 1970 two bull frogs were successfully injected into earth orbit by means of a four stage Scout rocket assembly launched from the NASA launching site on Wallops Island Virginia, USA They were housed in a satellite housing a Frog Orbital Experimental Package (FOEP) totally immersed in oxygenated water and serviced by an automatically controlled life support system. Also included in the package was a centrifuge and the electronic equipment necessary for telemetered transmission of signals encoding the amplified action potentials from selected otolith-controlled axons of the vestibular branches of the labyrinths the electrocardiogram of each frog the output of the centrifuge accelerometer and a time signal as well as various engineering data. A tape recorder accumulated data which were collected by 6 telemetry stations around the world which received and relayed the stored data on overflight.

An internal report of the technical and biological aspects of the mission has been submitted to NASA (Gualtierotti Bracchi & Rocca 197?) This report also contains a preliminary assessment of the results available at that time

The rationale underlying this bioprobe experiment was to study the effects of "free fall" or "weightlessness on a sense organ specifically evolved to respond to changes of the orientation of the animal's head within the earth-gravitational field of 1 g What, if any changes would be observed in the basic activity of the organ and in its mode of response to imposed linear acceleration in orbital flight (10^{-4}–10^{-} g max.)?

In this mission transmission of data was monitored from space for six days which was the expected maximum period of proper functioning of the electric storage batteries supplying the life support and monitoring systems

The computer analysis of the wealth of telemetered data as well as of the data obtained from the preparations before the flight has now progressed far enough to allow of a comparative interpretation in terms of vestibular physiology of the recorded behaviour of four otolith-controlled units on the ground and in orbit both at rest and when exposed to centripetal acceleration by means of various schedules of standard centrifuge cycles programmed in advance and automatically executed during the flight

SUMMARY OF METHODS

In view of the inaccessibility of the internal NASA report, it will be necessary to summarize the most important points of method The selection of frogs the viability tests and the various stages of the operative procedure before the implantation of the "neutral buoyancy electrodes (Gualtierotti & Bailey 1968) as well as the implantation and instrumentation of these electrodes have been described by Gualtierotti & Gerathewohl (1965) and Gualtierotti & Alltucker (1966) in connection with experiments on the effect of "free fall" on otolith organs of the bull frog in parabolic flight. Since then all these techniques were further refined in preparation for the orbital flight experiment to be dealt with in the present paper

Essential points of these methods may be summarized as follows

1 The neutral buoyancy electrode is essentially a tungsten microelectrode sharpened with the technique developed by Hubel (1957). It has an attachment of polyethylene

ture maintained when in space within the range of 17°C±1.5°C The gas circulation system is filled with pure O_2 supplied by an O_2 bottle through a demand regulator the gas exchange takes place through an especially designed lung providing a large surface by means of several sheets of thin silicon rubber These are highly permeable to O_2 CO_2 and water vapour

The CO_2 is eliminated from the gas by absorption through a bed of barium hydroxide The circulation of the gas and water system is assured by two small pumps. The container for the biological preparations through which the water circulates passing through a filter system covering its entire walls forms the arm of a centrifuge that provides if needed angular and centripetal acceleration at the sites of the labyrinths of the two frogs placed tail to tail

The pressures in the gas and water compartments are equalized by an accumulator system This consists of a container with 2 chambers divided by a collapsible partition set to insure equilibrium of the pressures between gas and water

The appropriate water temperature is maintained by a thermostat and a heat exchanger The cooling is achieved by evaporation into the space vacuum and the heating by an appropriate heater The temperature control was manually operated not automatic but capable of being operated by telemetry In pre-flight on the ground cool air is pumped over the FOEP as the cooling system could not function in the atmosphere

During extended experiments carried out on the ground the FOEP was placed in a thermoregulated room The water temperature and pressure were controlled continuously

The biological signal was recorded through an emitter-follower (Gualierotti & Gerathewohl 1965) which was connected to the frog s jaw and the signal was amplified by the main amplifiers to the voltage level appropriate for telemetry

The FOEP was encased in an air-tight canister containing air at the pressure of 1 atm both during the flight and on the ground

TELEMETRY

An appropriate telemetry system with a frequency response up to 2000 Hz was especially provided in the spacecraft to transmit the vestibular pulses

Data transmitted through the entire system included vestibular activity (four channels) ECG (two channels) the centrifuge accelerometer output water temperature casing pressure water pressure

PREPARATION FOR THE FLIGHT

As the main problem was precise timing and there was a need for being ready for a repeat mission in case of failure with a minimum turn-round time a group of 24 frogs were prepared with the purpose of having at least six of them ready at any given time

As the animals were kept in O_2 saturated water the frogs were already partially saturated with O_2 and this decreased the flushing time of the FOEP after the animals were placed into it (see below)

Twelve hours before transportation to the launching pad two of the frogs were placed in the FOEP The gas system of the FOEP was then flushed through an open loop oxygen circuit to dispose of the residual nitrogen in the frogs and in the water that might have accumulated during the handling of the package and of the resulting bubbles of air the presence of nitrogen in fact would have decreased the PO_2 in the gas circuit the capacity of which was limited

Periodical samples of centrifuge water were tested for oxygen content. The open oxygen loop was maintained till the PO_2 reached approximately 700 mmHg. The loop was then closed and the system supplied by the FOEP oxygen bottle through a demand valve that

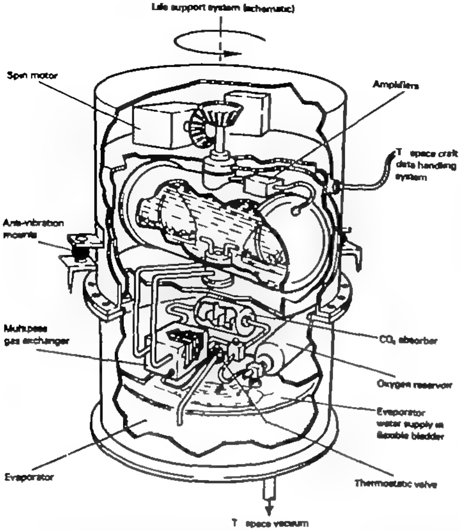

Fig 1 Schematic drawing of the FOEP (Frog Otolith Experiment Package) The life support system is shown including the gas exchanger (O_2–CO) the CO_2 absorber (Bariumhydroxide) the oxygen reservoir with a demand valve The two shapes drawn opposite the outlets of the gas exchanger pipes symbolize the position of the two frogs in the water-filled container Further description in the text

microtube containing an air bubble serving to equate the total density of the electrode with the density of the tissue in which it is to be embedded This makes the electrode nerve contact immune against the effect of the high g forces on blast-off (10 g thrust acceleration) and 2–600 Hz sinusoidal vibration at 1 g The successful recording from implanted vestibular units for a period of six days after injection into orbit bears witness to the excellent quality and reliability of this type of neutral-buoyancy electrode

2 The normal appearance of the ECG monitored during the entire mission in one frog and for 40 hours in the other shows that as on the ground the immersion in water of a PO_2 temperature ratio of 700 mmHg/16 5–17.5°C maintained the frogs in a state of physiologically adequate skin respiration compatible with normal activity of neuro-sensory systems

THE FOEP AND LOADING PROCEDURE

The FOEP or Frog Orbital Experiment Package is a compact unit (Fig 1) composed of three different systems A life-support system divided into water and gas circulation which assures a water environment with the appropriate filtered flow (300 ml per minute) a PO_2 between 650–700 mmHg and a tempera-

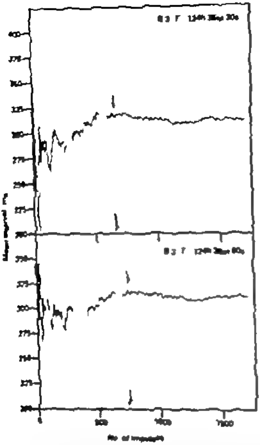

Fig. 3. Determination of the statistically significant sample by means of the sequential mean of the interspike intervals. At the arrow, the curve becomes flat and parallel to the abscissa corresponding to 750 intervals approximately. This is empirically taken as significant sample. The bottom record is equivalent to the upper one but the sampling started 30 later.

the nearest receiving station, edited and analysed through a Univac computer to provide a more limited program (e.g. acceleration profile, time history and mean interspike interval).

It is obvious that visual inspection on the original analogue tapes is not feasible in long experiments of this sort in which hundreds of thousands of data are involved. The following technique was, therefore, used (Fig. 2). During tape editing the first impulse triggered a square pulse of 0.5 msec and the time base. These were continuously recorded on a storage oscilloscope. The spike immediately following would appear at a given time after the first. In this way the interval between the consecutive spikes was immediately evident and any pulse that happened to occur within the minimum interval typical of the unit (3 to 6 msec) would indicate either an artifact or an additional biological signal. Such a technique has the advantage that the entire series of data can be run continuously with an immediate possibility of checking any unwanted event. This technique facilitated the following procedures.

(*a*) Identification of bursts of noise and artifacts due to frog movements, telemetry gaps and any other superimposed event. The timing of such events or noise was noted through the time code recorded on a separate channel of the magnetic tape and the computer was instructed to ignore data recorded within the identified period of artifacts.

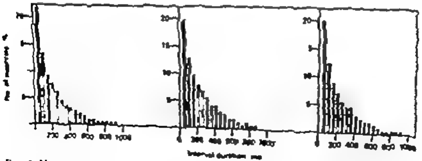

Fig. 4. Using maximum sample as determined by the method shown in Fig. 3 the interspike-interval distribution is studied by means of interspike-interval histograms of three different samples. They are very similar. The sampling technique therefore is considered to be correct.

maintained the required pressure The water PO_2 was tested again and this procedure repeated several times till the PO_2 was maintained at slightly above 700 mmHg The FOEP was then ready to be placed into its cannister This having been done ground control data were acquired and stored on magnetic tape Such data were

1 20 minutes of activity of the four vestibular units at rest

2 A number of single centrifuge spin cycles several minutes apart

3 A number of quadruple cycles during which the centrifuge was restarted as soon as it stopped

4 30 additional minutes of data immediately following the last centrifuge cycle

DESCRIPTION OF MISSION

During the entire period *preceding the lift off* the activity of the four vestibular units and the ECG of the two frogs were tested periodically through telemetry The data were recorded on a strip chart and on magnetic tape Starting approximately from 10 min before the lift off data were recorded continuously and the recording was carried out without interruption *through the entire lift off up to injection in* orbit till the time at which the satellite disappeared beyond the horizon outside the reach of the ground recording antenna No data could be obtained during the first orbit (90 min) owing to a command failure which was rectified from the second orbit onward

Data Handling and Analysis

All data (vestibular ECG time code and accelerometer) were transferred to digital magnetic discs by an IBM 1800 computer The time code (hour–minute–seconds) was memorized second by second along with biological data and constituted the main reference for data retrieval During A/D conversion the main code was used also to instruct the computer through punched cards to disregard all the periods where noise of any source (telemetry gaps *muscular noise*) was detected Different programs were developed to provide for

1	Sample duration	sec

During the orbital experiment it had to be decided within a few hours which experimental routine was to be followed next depending upon the behaviour of the vestibular units For this purpose data were collected directly from

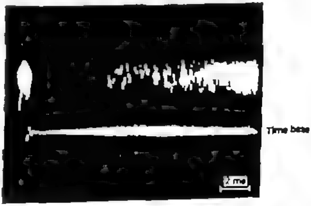

Fig 2 Identification of the minimum impulse interval from continuously running data tape for the purpose of confirmation of true single-unit recording Each impulse triggers a 0.5 ms square wave The first impulse starts the time base of a storage oscilloscope If the activity of one unit only is recorded a significant gap will follow the triggering impulse in this case of approx 5 ms If more than one unit is present no such gap will appear as the intervening signal will fill up entirely the time after the first triggering impulse This method allows continuous identification of any number of impulses belonging to a single unit

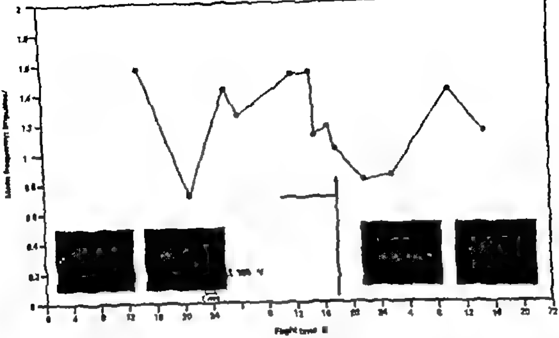

Fig. 3. Effects of slow increase of oxygen tension up to 1.7 atm in the FOLP water on the firing rate and configuration of action potentials of a statoreceptor unit. The arrow indicates the end of the increase in pressure after 8 hours. Water temperature 16.5–17 °C. Ordinate: Mean frequency of 2000 impulses for each point. Abscissa: Duration of experiment in hours. Inserts: Sample of impulses before (left) and after pressurization (right).

All conditions and test procedures were the same with the exception of the existence of the earth-gravitational field of 1 g. 5 units were studied for 170 hours recording at 1 hour intervals during day and night. After the successful flight four additional units were studied for 48 hours with recordings made for 15 min every 45 min.

The receptors were identified as tonic statoreceptors when they showed a response significantly representative of the different steady-state spatial positions of the head (I

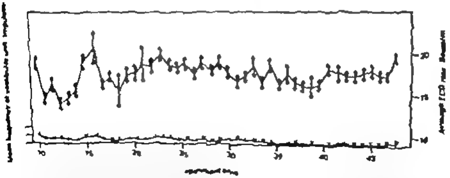

Fig. 4. ECG (ordinate on right) and statoreceptor firing rate (ordinate on left) during 48 hours of recording on the ground. The frog was kept at a water temperature of 17–18 °C. The unit responded throughout the experiment to just above threshold vibration of the water pump (for detail see text). Recording every 15 minutes in the hour. Mean and standard deviation both for ECG (black lozenges) and discharge frequency (empty triangles) (1000 impulses for each point).

(*b*) Adjustment of a clipping level in order to make sure that no additional unwanted biological signal might be computed For biphasic potentials with a sizeable second phase opposite to the main pulse a double clipping technique was used

With a large amount of spike train data the *chief problem was to determine a statistically* significant sample This is very difficult and a satisfactory solution has not been found The calculation of the sequential means was used for this purpose (Fig 3) *Alternatively the* interspike interval distribution could be evaluated by means of interspike interval histograms in different samples of the same number of events (Fig 4) For a steady state activity (no trend detected) the distribution appeared to be closely the same and the corresponding number of intervals were taken as being sufficient for a statistically significant sample

Results

ASSESSMENT OF THE FROG S CONDITION UNDER WATER IN THE FOEP O_2 CONSUMPTION

A frog of known weight and prepared as for the flight except for the chronic microelectrodes implantation was placed in the FOEP kept at various constant temperatures (between 10° and 25°C) to measure the oxygen consumption as a function of the environmental PO_2 in the bath water changing it from 700 to 400 mmHg in steps

When the limbs were paralyzed by cutting the branches of the sacral and thoracic plexuses there was normal consumption of oxygen (160–180 ml O_2 h/kg) at a PO_2 of between 600 and 700 mmHg in the environmental water at a temperature of 16 5–17 5°C These parameters are identical with those maintained during the orbital flight Below 500 mmHg and especially on a sharp decrease over the range between 550 and 500 mmHg the oxygen consumption decreased to an average of 30 ml/h/kg Distress symptoms became evident after approximately two hours signalled by an increase of the amplitude and duration of the T wave of the ECG In this condition the frog survives for some hours only

The ambient temperature is critical Changes towards the lower and upper limits of the above mentioned range produce irregularity of the heart rate and changes in the amplitude and duration of the R waves Most of these changes are reversible but recovery may take many hours

At nearly 1 atm of PO_2 oxygen poisoning *might be expected to take place during an exposure* of several days

That this does in fact not occur was demonstrated by increasing the PO_2 in the FOEP to 1 7 atm and comparing the ECG as well as the amplitude and shape of the vestibular action potentials and the firing rate at normal and increased O_2 pressure for 3–5 days No effects were found (Fig 5) and the O_2 consumption remained unaltered

THE ACTIVITY OF THE VESTIBULAR STATORECEPTORS

A On the ground (1 g)

The activity of single statoreceptors (20 units) of the labyrinth of the bull frog in air studied for 10–48 hours has been described elsewhere (Gualtierotti 1968) In the present paper the description will be limited to the impulse train data recorded from single vestibular nerve fibres activated by statoreceptors in frogs kept under water within the FOEP This apparatus is identical to the one which was used for the investigation of the effect of "weightlessness during the 6 1/2 days orbital flight of the OFO A experiment

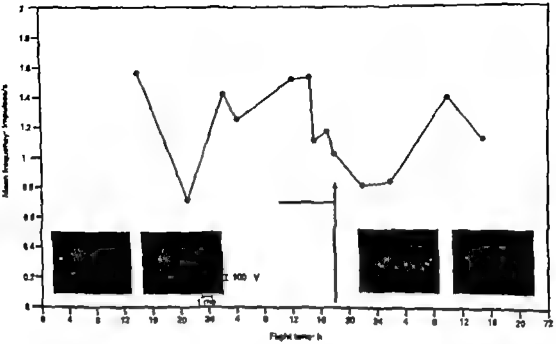

Fig. 5. Effect of slow rise of oxygen tension up t 1.7 tm in the FOEP water on the firing rate and configuration of action potentials of statoreceptor unit. The arrow indicates the end of the rise in pressure after 8 hours. Water temperature 16.5–17.2°C. Ordinate: Mean frequency of 000 impulses for each point. Abscissa: Duration of experiment in hours. Insert: Sample of impulses before (left) and after pressurization (right).

All conditions and test procedures were the same with the exception of the existence of the earth-gravitational field of 1 g. 5 units were studied for 170 hours recording at 12 hours intervals during day and night. After the successful flight four additional units were studied for 48 hours with recordings made for 15 min every 45 min.

The receptors were identified as tonic statoreceptors when they showed a response significantly representative of the different steady-state spatial positions of the head (r

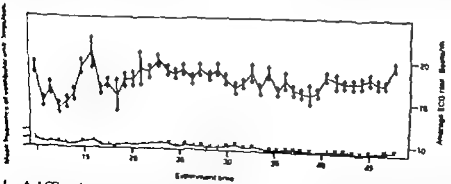

Fig. 6. ECG (ordinate on right) and statoreceptor firing rate (ordinate on left) during 48 hours of recording on the ground. The frog was kept at water temperature of 17.0°C. The unit responded throughout the experiment to just-above-threshold vibration of the water pump (for detail see text). Recording every 15 minutes to the hour. Mean and standard deviation both for ECG (black lozenges) and discharge frequency (empty triangles) (7 000 impulses for each point).

(*b*) Adjustment of a clipping level in order to make sure that no additional unwanted biological signal might be computed For biphasic potentials with a sizeable second phase opposite to the main pulse a double clipping technique was used

With a large amount of spike train data the chief problem was to determine a statistically significant sample This is very difficult and a satisfactory solution has not been found The calculation of the sequential means was used for this purpose (Fig 3) Alternatively the interspike interval distribution could be evaluated by means of interspike interval histograms in different samples of the same number of events (Fig 4) For a steady state activity (no trend detected) the distribution appeared to be closely the same and the corresponding number of intervals were taken as being sufficient for a statistically significant sample

ASSESSMENT OF THE FROG S CONDITION UNDER WATER IN THE FOEP O_2 CONSUMPTION

A frog of known weight and prepared as for the flight except for the chronic microelectrodes implantation was placed in the FOEP kept at various constant temperatures (between 10° and 25°C) to measure the oxygen consumption as a function of the environmental PO_2 in the bath water changing it from 700 to 400 mmHg in steps

When the limbs were paralyzed by cutting the branches of the sacral and thoracic plexuses there was normal consumption of oxygen (160–180 ml O_2 h/kg) at a PO_2 of between 600 and 700 mmHg in the environmental water at a temperature of 16 5–17 54°C These parameters are identical with those maintained during the orbital flight Below 500 mmHg and especially on a sharp decrease over the range between 550 and 500 mmHg the oxygen consumption decreased to an average of 30 ml/h/kg Distress symptoms became evident after approximately two hours signalled by an increase of the amplitude and duration of the T wave of the ECG In this condition the frog survives for some hours only

The ambient temperature is critical Changes towards the lower and upper limits of the above mentioned range produce irregularity of the heart rate and changes in the amplitude and duration of the R waves Most of these changes are reversible but recovery may take many hours

At nearly 1 atm of PO_2 oxygen poisoning might be expected to take place during an exposure of several days

That this does in fact not occur was demonstrated by increasing the PO_2 in the FOEP to 1 7 atm and comparing the ECG as well as the amplitude and shape of the vestibular action potentials and the firing rate at normal and increased O_2 pressure for 3–5 days No effects were found (Fig 5) and the O_2 consumption remained unaltered

THE ACTIVITY OF THE VESTIBULAR STATORECEPTORS

A On the ground (1 g)

The activity of single statoreceptors (70 units) of the labyrinth of the bull frog in air studied for 10–48 hours has been described elsewhere (Gualtierotti 1968) In the present paper the description will be limited to the impulse train data recorded from single vestibular nerve fibres activated by statoreceptors in frogs kept under water within the *FOEP This apparatus* is identical to the one which was used for the investigation of the effect of "weightlessness" during the 6 1/2 days orbital flight of the OFO A experiment

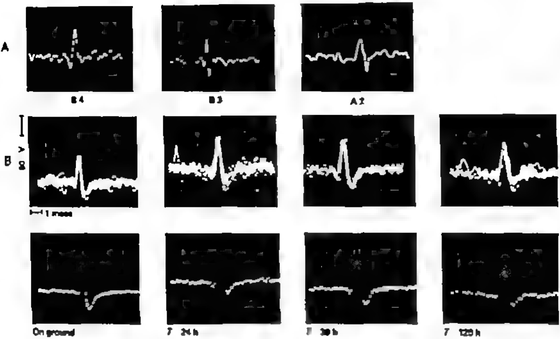

Fig. 8. (A) Samples of impulses from units B4, B3 and A2. They are different in shape and duration and easily recognizable. (B) Identification of B3 impulse data during the flight from T+9 h to T+120 h. Upper record: Superposition of a number of successive impulses. Lower tracing: Computerized average of 60 impulses. The telemetering system altered the spike shape slightly in comparison with the ground data. Owing to the lower frequency response of the telemetry system the spikes are flatter and longer in duration. The general parameters are however maintained unaltered throughout the flight.

ficient of variation remained consistently 1±0.1 for all units. Thus within the limits of this rather large variability the general characteristics of the basic activity at rest even in this preparation with all feedback systems intact (closed-loop) remained constant for several times the 24 hours cycle. A constant trend toward decreased activity indicates however that the preparation cannot be considered to be absolutely physiologically normal. The above statements are valid for a period starting no sooner than hours after the microelectrode implantation and for all the time in which the preparation is maintained in good condition (Gualtierotti & Alltucker 1966).

B. In orbit (10^{-4} g max in all directions)

The OFO A experiment was conducted on two frogs (A and B) of approximately 0.350 kg weight with one microelectrode each implanted in the right and left vestibular nerves. Accordingly the units were identified as A1, A2, B3, B3a, B4.

Physiological condition

The condition of the preparations was continuously checked by inspection of the ECG. This was particularly easy for Frog B as the ECG was clear from noise all the way through the experiment, whereas for Frog A electric noise appeared after 24 hours of flight to such an extent that at T+48 the ECG was difficult to recognize. It was felt, therefore, that the analysis of unit A2 should be limited to the first 40 hours of the flight, as insufficient indication of the animal's condition laid the interpretation of the observed changes open to doubt. Unfortunately the records from unit A1 proved to be completely unsuitable for

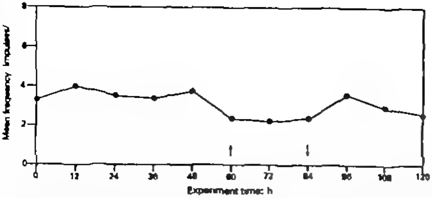

Fig 7 Ground control experiment Frog at constant temperature 17°±0.5°C The activity at rest of a single statoreceptor unit recorded for 120 hours, 30 minutes every 1 hours at the same time of the day Each dot corresponds to the average frequency of 000 spikes The arrows indicate sudden spontaneous shift of the frequency of discharge at rest by about 50%

test and trend evaluation) Directionally the receptors presented here were fairly homogeneous i e they responded to head down positions beyond an angle of 10° downward from the normal" plane In the bench position of the FOEP the animal s spatial orientation was normal" and no above threshold gravity component was included in the receptor field of these units In the orientation of the second batch of units studied after the flight one unit only showed changes in activity locked on to the minute vibration of the water pump as measured near the head (1–3 g 10^{-3} sinusoidal with a 20 msec period (Fig 6))

This unit was studied in order to compare its activity with unit B_2 that during the OFO A flight had become sensitive to a similar stimulus for a period of time (see later) All the tested frogs which were kept in good physiological condition showed an activity in the majority of fibres approached When it was difficult to find active fibres in the nerve during the microelectrode implantation procedure it was found that some deterioration of the preparation was in progress normally due to hypoxia in fact good oxygenation restored lively and constant activity throughout the nerve

Average rate of firing

All units studied showed a low rate of firing at rest with a range of between 1 and 4 impulses/sec The same pattern was recorded under water as in air The time history of the average rate of firing during several days did not show an increase in the general variability (Fig 7) It should be noticed that the environment was constant within very close limits The frogs were kept in perfect darkness throughout the experiment in a sound proof environment submerged in CO_2-free water at a temperature constant within 0 5°C with a steady PO_2 and hydrostatic pressure

Even under these conditions the definition at rest has to be clarified here it signifies that the proper input (acceleration) had a subthreshold value

The unit responding to the pump vibration (Fig 6) showed a rate of firing of the same order as that shown at rest (approximately 2 impulses/sec) The response to such a liminal stimulus consisted in the phase-locked synchronization with the vibration frequency (50 Hz)

This behaviour was constant throughout the entire 48 hours of recording during which the vibratory stimulus maintained the same parameters

Interval distribution and coefficient of variation

For each unit the interspike interval distribution (see Fig 4) as shown by the minimum interval and the mode remained closely unaltered during the entire experiment The coef

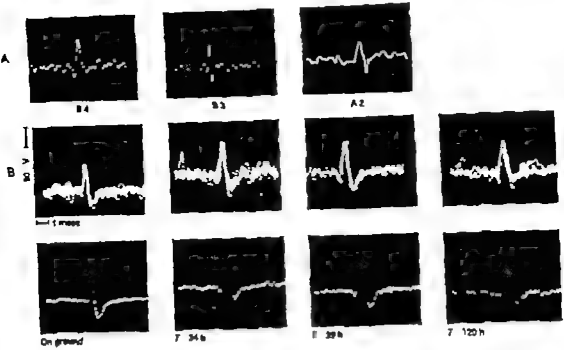

Fig. 8. (A) Samples of impulses from units B4, B3 and A2. They are different in shape and duration and easily recognizable. (B) Identification of B3 impulse data during the flight from *T*+9 h to *T*+120 h. Upper record: Superposition of a number of successive impulses. Lower tracing: Computerized average of 60 impulses. The telemetering system altered the spike shape slightly in comparison with the ground data. Owing to the lower frequency response of the telemetry system the spikes are flatter and longer in duration. The general parameters are however maintained unaltered throughout the flight.

ficient of variation remained consistently 1 ± 0.1 for all units. Thus within the limits of this rather large variability the general characteristics of the basic activity at rest even in this preparation with all feedback systems intact (closed-loop) remained constant for several times the 24 hours cycle. A constant trend toward decreased activity indicates however that the preparation cannot be considered to be absolutely physiologically normal. The above statements are valid for a period starting no sooner than 2 hours after the microelectrode implantation and for all the time in which the preparation is maintained in good condition (Gualtierotti & Alltucker 1966).

B. In orbit (10⁻ g max in all directions)

The OFO A experiment was conducted on two frogs (A and B) of approximately 0.350 kg weight with one microelectrode each implanted in the right and left vestibular nerves. Accordingly the units were identified as A1, A2, B3, B3a, B4.

Physiological condition

The condition of the preparations was continuously checked by inspection of the ECG. This was particularly easy for Frog B as the ECG was clear from noise all the way through the experiment, whereas for Frog A electric noise appeared after 24 hours of flight to such an extent that at *T*+48 the ECG was difficult to recognize. It was felt, therefore, that the analysis of unit A2 should be limited to the first 40 hours of the flight as insufficient indication of the animal's condition laid the interpretation of the observed changes open to doubt. Unfortunately the records from unit A1 proved to be completely unsuitable for

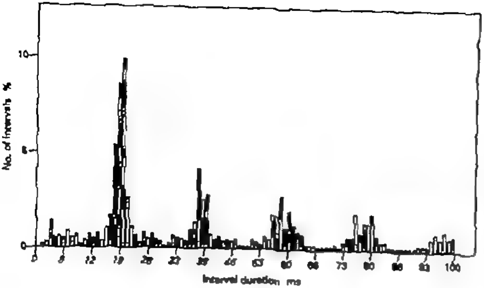

Fig 9 Interspike-interval histogram of unit B3 which during this period responded to the water pump vibration. The peaks shown in the figure correspond exactly to the 1870 revolutions per minute of the pump

analysis Fig 8 shows that the units selected for analysis retained identical parameters throughout 120 h of observation Of the four units examined units A2 and B4 were at rest when not specifically stimulated by a centrifuge cycle Units B 3 and B 3 a showed a response to the vibration of the waterpump during some period of the flight The response to the pump vibration is demonstrated by typical peaks (20 msec apart) on the interspike histogram of the unit (Fig 9) The vibratory stimulus thus resulted in an effective input of sufficient strength to increase the average firing rate above the level recorded on the ground

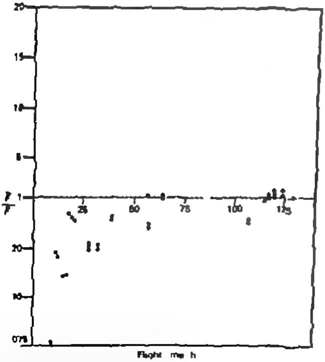

Fig 10 Unit B4 Change the ratio of the mean frequency during the flight ($\bar{F}$) and the mean frequency at rest ($\bar{F}$) during 130 h of orbital flight Note the change in the rate of firing from a decrease of 1/15 to a peak increase of 20 times the mean frequency on the ground

All units showed in free fall a highly significant periodic change in activity of up to 20 times larger than the occasional fluctuations on the ground Fig 10 and 11 show such periodic fluctuations in activity for unit B 4 for up to 125 h and for unit A 2 for up to 40 h after injection into orbit Both units were free from external stimulation except when the centrifuge was activated When first observed the level of activity was considerably lower than that on the ground in both units The impulse activity is here expressed as the quotient of average activity in flight over average activity on the ground (F/F_0) The whole period of observation of unit A 2 falls within the period of reduced activity

In unit B 4 the initial period of reduced activity is followed by a large increase in the impulse discharge which lasts for approximately 50 h This is then followed by a second reduction in activity which in turn leads to a level of activity commensurate with that observed on the ground

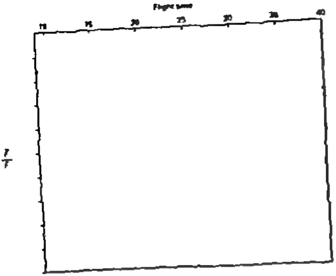

Fig. 11. Unit A 2 (same representation as in Fig. 10). During the flight the mean rate of firing at rest decreases progressively. F = mean frequency in orbit. F = mean frequency on the ground.

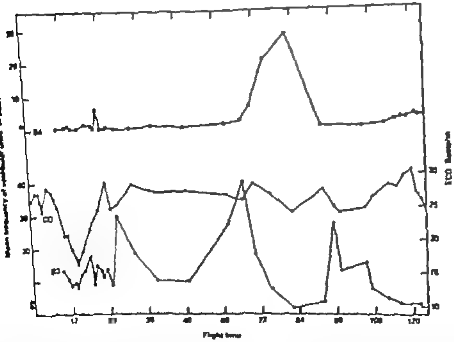

Fig. 12. Time history of the rate of firing during 125 h of orbital flight of units B 3 (lower record, round dots) and B 4 (upper record, square dots) and ECG of frog B (middle record, black triangles). On the left, outside the ordinate, mean frequencies on the ground (diamonds). All points represent the mean of 2000 impulses. Unit B 3 was stimulated by the vibration of the water pump, unit B 4 was not affected. Note the large decrease of the heart rate between T 9 h and T 4 h caused by a drop in the water temperature to 13°C due to faulty command to the thermoregulatory system. From T 4 h onwards the temperature control was working perfectly and the temperature was maintained between 16.5° 17°C.

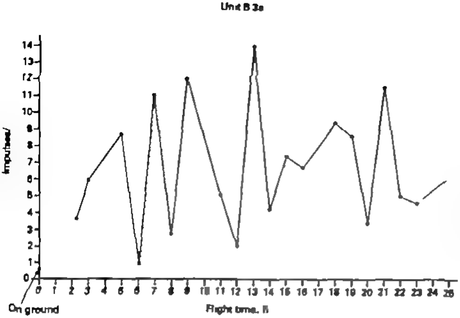

Fig 13 Changes of the intercycle frequency of firing during the first 25 h of the flight of unit B 3 a Periodical increase and decrease of frequency are shown up to nearly 10 times the activity level on the ground

Observation of numerous otolith-controlled units showed that the "basic" activity includes not infrequently bursts of a few closely spaced impulses representing intraburst frequencies up to 200 impulses/sec (Gualtierotti & Alltucker 1966) In orbit the incidence of such "bursts" increases to such an extent in unit B 4 that the whole of the "basic" activity may consist of frequent "bursts" alternating with periods of complete inactivity

Unit B 3 (also B 3 a (see page 20)) were sensitive to the vibration of the circulation pump (Fig 9) Their behaviour and that of unit 4 B is illustrated by Fig 12 and 13 for 120 h (B 4 and B 3) and 25 h (B 3 a) respectively It should be noted that the behaviour of unit B 3 a mirrors that of unit B 3 for the whole period of its evaluation As shown in Fig 12 there are large fluctuations in the activity of unit B 3 not only while it responds to pump vibration but also after approximately $T+80$ h when it ceases to do so For a few hours its level of activity now even drops below that recorded on the ground A scale factor accounts for the apparent absence of fluctuations in trace B 4 up to approximately $T+70$ h (compare however Fig 10)

Coefficient of Variation

The variation coefficients for units B 3 and B 4 of the same frog are very different The CV of B 3 is similar to the one typical of the units studied on the ground namely around 1 ± 0.1 while for B 4 owing to the frequent occurrence of "bursts" during the first 92 hours of flight the CV oscillated between 1 5 and 10 approx As soon as the "bursts" disappeared the CV returned to 1 (Fig 14) In unit A 2 and B 3 a the CV remained equal to 1 ± 0.1 throughout

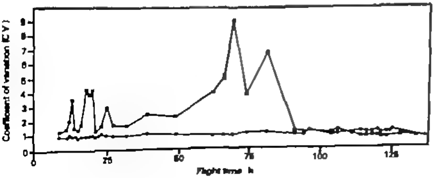

Fig 14 Coefficient of variation against time Unit B 3 (lower record round dots) and B 4 (upper record square dots) during 130 h of orbital flight

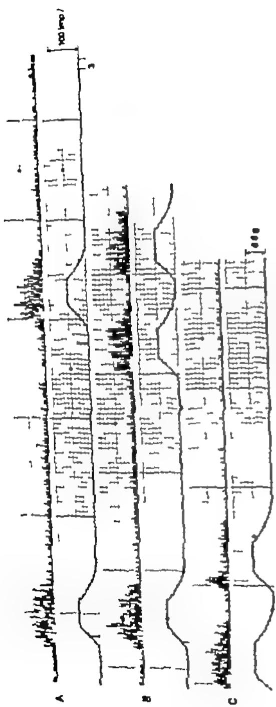

Fig. 15. Unit A on the ground. For explanation see the text.

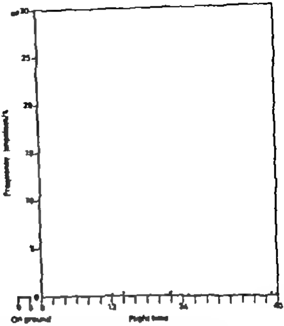

Fig. 16. Unit A in orbit. Analysis of the activity at rest and during the second half of the centrifuge cycle at constant speed. The mean frequency of samples of approximately 200 impulses at rest and 25 impulses during stimulation is given by the round and square dot respectively. The analysis is limited to the first 40 h of the flight. frog A after this time did not show readable ECG and its physical condition could not therefore be fully assessed. This unit did not respond to the water pump vibration and is truly at zero stimulation between the centrifuge cycles. There is a remarkable decrease in frequencies during the flight. The response to the spin cycles is also diminished. On the ordinate: Mean firing rate (impulses/sec). On the abscissa: Time in hours from lift-off. On the left of the ordinate, mean frequency at rest and response to the centrifuge cycles on the ground before the flight.

Responses to centrifuge spin cycles on the ground and in orbit

No data could be recorded during the first complete orbit (90 min) because of a temporary command failure which could fortunately be rectified from the second orbit onward. The responses of the various units to centrifuge spin cycles may now be described by selected examples taken from the case histories of the individual units.

Unit A2 yielding only 40 h of analysable flight record behaved on the ground as shown in Fig. 15. Trace A represents two slowly adapting tonic responses to centrifuge spin cy

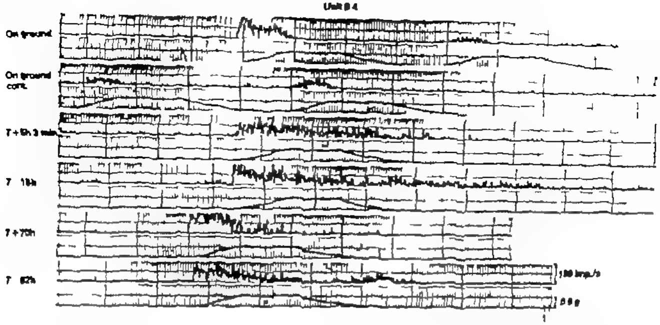

Fig. 17. Unit B 4 on the ground and in orbit. Description in the text.

cles at an interval of approximately two min showing similar characteristics. Traces B and C (10 h later). Two widely spaced and three closely spaced stimuli result in practically unaltered response types with a certain progressive diminution in total impulse output when the stimuli follow closely upon another. The behaviour of this unit during 40 hours of orbital flight is shown in Fig. 16. In contrast to unit A 2 unit B 4 behaved on the ground like a pronouncedly phasic unit with fairly rapid adaptation during the constant velocity period of the spin cycle. Traces 1st and 2nd from top of Fig. 17 illustrate this and the decline in gain on close repetition of stimulation. Trace 3rd ($T+5$ h 3 m) shows that the unit's behaviour has changed from phasic to tonic with the characteristically slow adaptation. Trace 4th ($T+15$ h) shows the unit's behaviour unchanged. At $T+70$ h there is a return to faster

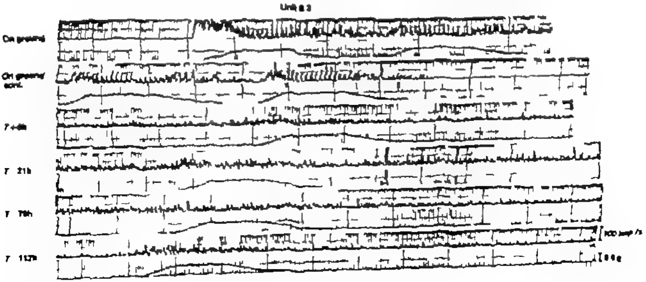

Fig. 18. Unit B 3 on the ground and in orbit. Description in the text.

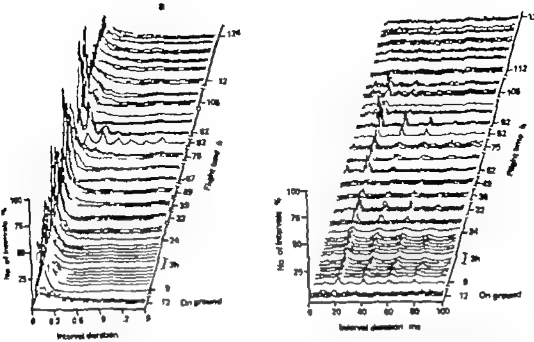

Fig. 19. Unit B3. Three-dimensional diagrams indicating the interspike-interval distribution by means of inter-spike interval histograms displaying data on the ground followed by data throughout the orbital flight. In *b* the histograms are based on smaller classes (ms) and in *a* on larger ones (s). The peaks of the histograms in *b* correspond to the bursts of impulses following the peak vibration curves. Their average distribution is given in *a*. It is immediately evident that the alteration in the basic activity of this unit starts with the first record available at $T+9$ h, the excursion and end around 110 h. From 11 to 124 h the histograms are similar to the ones obtained on the ground.

adaptation and the response following upon deceleration of the centrifuge is followed by a short rebound of the discharge which is not untypical for responses in orbit.

As unit B4 was unaffected by pump vibration it presents us together with the relatively short lived unit A with the most instructive picture of the behaviour of otolith-controlled vestibular units in weightlessness. The records making up Fig. 17 do not show much of the long-term periodic fluctuation in basic resting activity and do not therefore clearly illustrate the effect of such fluctuations on response gain. This is largely due to the fact that the mean frequency of the "basic" activity is composed of high-frequency "bursts" and long inactive periods.

Unit B3 having been for most of the orbital flight affected by pump vibration to which it responded by synchronized firing masking its basic resting activity cannot be considered to have been truly deprived of stimulation when at rest in "weightlessness". On the ground it behaved like a slowly adapting tonic receptor.

It showed a pronounced response to the fluctuation in gravitational stimulation (1 Hz) due to the deviation of the centrifuge platform from the true horizontal. It also showed a decrease in gain of its response to closely spaced repetition of the stimulus (Fig. 18, traces 1st and 2nd from top). Trace 3rd ($T+6$h) shows a response to the spin cycle against the background of a fluctuating ongoing response to the pump noise. The gain of the slowly adapting response is relatively small with only a moderate phasic component. There appears to be an unexplained start of increased activity approximately 6 sec before the recorded start of the

cles at an interval of approximately two min showing similar characteristics Traces B and C (10 h later) Two widely spaced and three closely spaced stimuli result in practically unaltered response types with a certain progressive diminution in total impulse output when the stimuli follow closely upon another The behaviour of this unit during 40 hours of orbital flight is shown in Fig 16 In contrast to unit A 2 unit B 4 behaved on the ground like a pronouncedly phasic unit with fairly rapid adaptation during the constant velocity period of the spin cycle Traces 1st and 2nd from top of Fig 17 illustrate this and the decline in gain on close repetition of stimulation Trace 3rd (*T*+5 h 3 m) shows that the unit s behaviour has changed from phasic to tonic with the characteristically slow adaptation Trace 4th (*T*+15 h) shows the unit s behaviour unchanged At *T*+70 h there is a return to faster

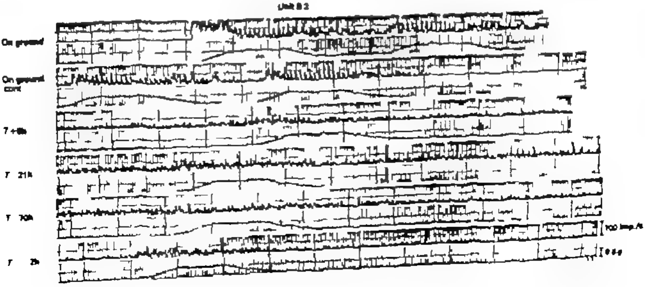

Fig 18 Unit B 3 on the ground and in orbit Description in the text

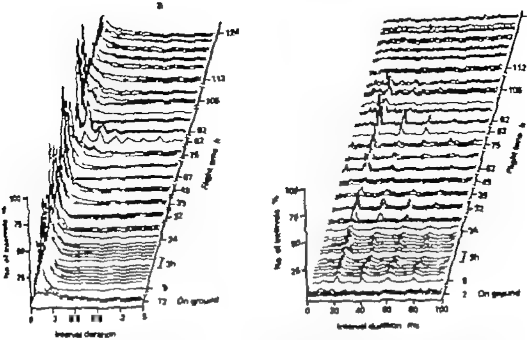

Fig. 19. Unit B3. Three-dimensional diagrams indicating the interspike-interval distribution by means of inter-spike-interval histograms displaying data on the ground followed by data throughout the orbital flight. 1 . . . b the histograms are based on smaller classes (ms) and in . . . on larger ones ( ). The peak of the histograms . . . b correspond to the bursts of impulses following the peak . . . duration curves. Their . . . erage distribution is given in . . . It is immediately evident that the alteration in the basic activity of the unit starts with the first record available at $T+9$ h in the mission and ends around 110 h. From 112 to 124 h the histograms are similar to the ones obtained on the ground.

adaptation and the response following upon deceleration of the centrifuge is followed by a short rebound of the discharge which is not untypical for responses in orbit.

As unit B4 was unaffected by pump vibration it present us together with the relatively short lived unit A2 with the most instructive picture of the behaviour of otolith-controlled vestibular units in "weightlessness". The records making up Fig. 17 do not show much of the long-term periodic fluctuation in basic resting activity and do not therefore clearly illustrate the effect of such fluctuations on response gain. This is largely due to the fact that the mean frequency of the "basic" activity is composed of high-frequency "bursts" and long inactive periods.

Unit B3 having been for most of the orbital flight affected by pump vibration to which it responded by synchronized firing masking its basic resting activity cannot be considered to have been truly deprived of stimulation when at rest in "weightlessness". On the ground it behaved like a slowly adapting tonic receptor.

It showed a pronounced response to the fluctuation in gravitational stimulation (1 Hz) due to the deviation of the centrifuge platform from the true horizontal. It also showed a decrease in gain of its response to closely spaced repetition of the stimulus (Fig. 18, traces 1st and 2nd from top). Trace 3rd ($T+6$h) shows a response to the spin cycle against the background of a fluctuating ongoing response to the pump noise. The gain of the slowly adapting response is relatively small with only a moderate phasic component. There appears to be an unexplained start of increased activity approximately 6 sec before the recorded start of the

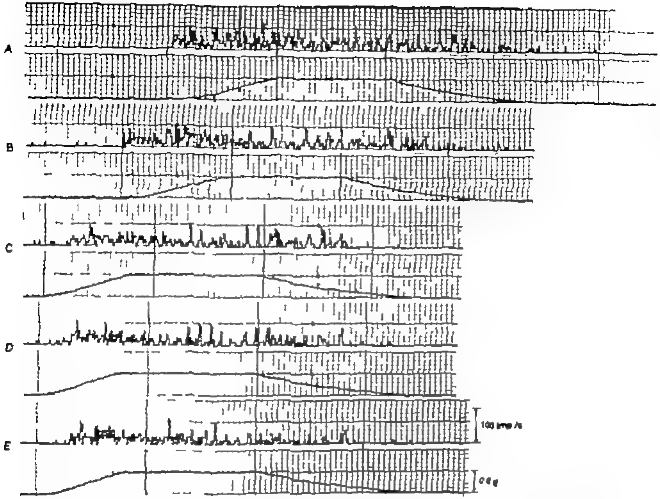

Fig 20 Unit B3a Responses on the ground (A and B) Two responses separated by a 20 minute interval followed by C D and E consecutive without a break The behaviour is similar to the one exhibited by unit B3 v z a decrease in the amplitude and in the gain in responses to closely spaced spin cycles This non-adapting unit is a good example of a tonic receptor

spin cycle This is most likely due to a fluctuation in the response to pump noise and only coincidentally related to the stimulus

Trace 4th ($T+21$ h) The response is the same as on trace 3rd but of moderately larger amplitude The large artifacts on both associated traces are an intrusion of house keeping data into the response picture

Trace 5th ($T+70$ h) The response to the spin cycle has become almost insignificant shows that against the background of a very lively pump response

Trace 6th ($T+112$ h) The response to the pump vibration has now disappeared (Fig 19b) and the spin cycle evokes a phasic tonic response of medium gain

During the analysis of the flight record of unit B3 it became clear that the electrode had picked up a well recognizable discharge from a second unit (B3a) This unit could be separately evaluated by the use of a spike recognition procedure It appeared to be less affected by the pump vibration and showed slowly adapting phasic tonic responses to the spin cycle with a relatively good gain Figs 20 and 21 show the responses of this unit on the ground and in orbit respectively the orbital data being set against simultaneous data from unit 3B It should be noted that at $T+15$ h the response of unit 3Ba has become temporarily phasic This is of special interest because this unit showed a pronounced slow adaptation on the ground The two units here compared change their mode of behaviour independent

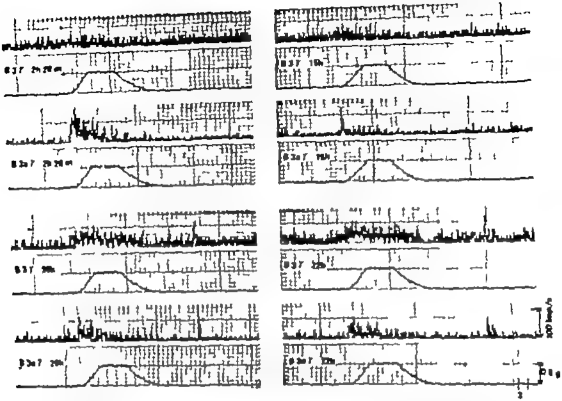

Fig. 21. Responses to the same centrifuge spin of two units B3 and B3 recorded from the same microelectrode during the orbital flight. Both units are tonic receptors and both did not respond to the water pump vibration on the ground but started responding to it in orbit. Note how both the intercycle activity and the responses to the centrifuge spin vary independently during the flight. In both units correlation seems to exist between the intercycle rate of firing and the amplitude of the response to the centrifuge spin cycle (see B3 T h 28 m compared with T+20 h and T 22 h, and unit B3 at T+2 h 28 m compared with T 20 h). At T 15 h unit B3 shows an evident change to phasic behaviour which is reversed at T 22 h.

ly although they presumably are derived from closely adjoining axons. On the ground however they are functionally very much alike.

Discussion

METHODS

The experiments carried out both on the ground and in orbit were completely automatic, were planned in such a way as to last several days, were based on the recording of the action potentials of single units of the vestibular nerve of animals kept in good physiological condition and most of the environmental variables (temperature, PO_2, light, pressure etc.) were carefully controlled. A constant adequate stimulus could be applied periodically by a centrifuge according to a predetermined program that could be changed as a function of the results (preset stimulus).

The activity of the vestibular statoreceptors prepared for the flight was studied starting one day before launch and continuing during the orbital period for six days till the exhaustion of the power supply of the spacecraft. Thus seven days of recording became available derived from the same single

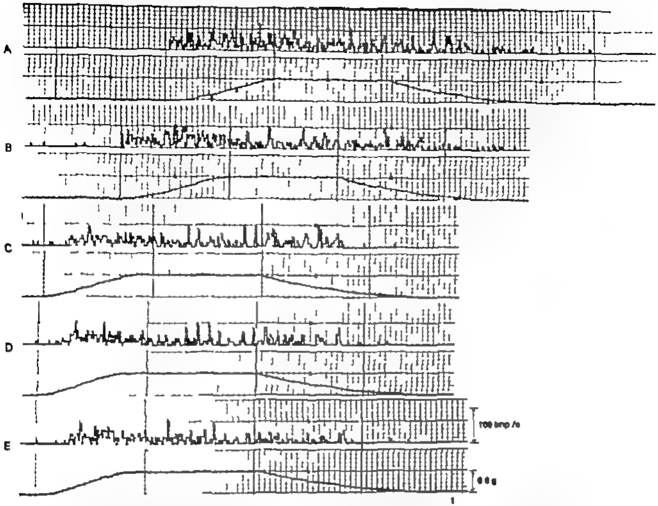

Fig 20 Unit B3a Responses on the ground (A and B) Two responses separated by a 20 minute interval fol lowed by C D and E consecutive without a break The behaviour is similar to the one exhibited by unit B3 viz a decrease in the amplitude and in the gain in responses to closely spaced spin cycles This non adapting unit is a good example of a tonic receptor

spin cycle This is most likely due to a fluctua tion in the response to pump noise and only coincidentally related to the stimulus

Discussion

METHODS

The experiments carried out both on the ground and in orbit were completely automatic, were planned in such a way as to last several days, were based on the recording of the action potentials of single units of the vestibular nerve of animals kept in good physiological condition and most of the environmental variables (temperature, PO_2, light, pressure etc.) were carefully controlled. A constant adequate stimulus could be applied periodically by a centrifuge according to a predetermined program that could be changed as a function of the results (preset stimulus).

The activity of the vestibular statoreceptors prepared for the flight was studied, starting one day before launch and continuing during the orbital period for six days till the exhaustion of the power supply of the spacecraft. Thus seven days of recording became available derived from the same single

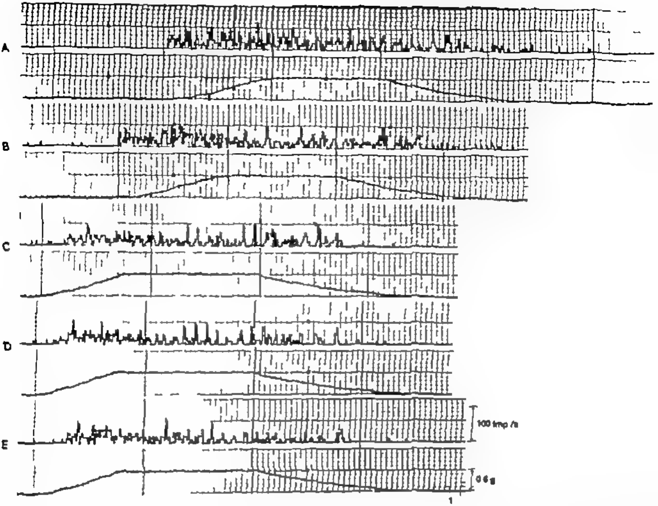

Fig 20 Unit B 3 a Responses on the ground (A and B) Two responses separated by a 70 minute interval followed by C D and E consecutive without a break The behaviour is similar to the one exhibited by unit B 3 viz a decrease in the amplitude and in the gain in responses to closely spaced spin cycles This non-adapting unit is a good example of a tonic receptor

spin cycle This is most likely due to a fluctuation in the response to pump noise and only coincidentally related to the stimulus

Trace 4th ($T+21$ h) The response is the same as on trace 3rd but of moderately larger amplitude The large artifacts on both associated traces are an intrusion of house keeping data into the response picture

Trace 5th ($T+70$ h) The response to the spin cycle has become almost insignificant shows that against the background of a very *lively pump response*

Trace 6th ($T+112$ h) The response to the pump vibration has now disappeared (Fig *19 b) and the spin cycle evokes* a phasic tonic response of medium gain

During the analysis of the flight record of unit B 3 it became clear that the electrode had picked up a well-recognizable discharge from a second unit (*B 3 a*) This unit could be separately evaluated by the use of a spike recognition procedure" It appeared to be less affected by the pump vibration and showed slowly adapting phasic-tonic responses to the spin cycle with a relatively good gain Figs 20 and 21 show the responses of this unit on the ground and in orbit respectively the orbital data being set against simultaneous data from unit 3 B It should be noted that at *T+15 h the* response of unit 3 B a has become temporarily phasic This is of special interest because this unit showed a pronounced *slow adaptation on* the ground The two units here compared change their mode of behaviour independent

reported so far in the literature are limited to relatively short-periods of acute experiments (Lowenstein & Roberts 1949 Rupert et al 1962 Kimm & Laschel 1971) There is no information on such activities observed for a sufficiently long time to analyse the general basic characteristics of the firing rate of the vestibular units for periods exceeding a possible daily cycle During the present experiments the impulse train data of the same single primary neurons of the vestibular statoreceptors have been recorded for the first time in a closed-loop system over a number of consecutive periods of 24 hours up to 6 in the carefully controlled environmental conditions provided by the FOEP

As a result the time history of the receptors activity could be studied as a function of the 24 hours span for a number of such cycles This would permit recognition of a possible rhythmical change

One may sum up the observations made on the four units in orbital flight as follows There is a significantly larger fluctuation of unit activity in the absence of the preset stimulus (centrifuge spin cycle) There is further a change in the gain of the response to the preset stimulus and to vibration. Thirdly there occur reversible changes in the mode of the response to the stimulus from tonic to phasic and vice versa. These observations appear to be exclusively associated with the condition of free fall because they have never to any significant extent been observed on the ground One may *therefore ask What is the chief effect of free* fall on the organ itself? There is no doubt that *the force* exerted by the otolith on the underlying otolith membrane or vice versa, the supporting force by the otolith membrane on the otolith organ is minimized by the absence of the gravitational acceleration vector The otolith mass however can be assumed *to be* unaltered at least *during* the period of the present run of observations *In the* earth gravitational field on the *ground one may imagine* the otolith membrane *to be tensioned by* the weight of the otolith supported by the suspension structures of the macula within the vestibulum. This may be assumed to result in a structural stiffening of the macula harbouring the orderly arrangement of the population of hair-cell receptors. It would be surprising if the mechanical properties of the macula were therefore not affected by the "unloading" of the macula in free flight It may be assumed that the macula so unloaded becomes a "play ball" of any random forces impinging upon it in orbit, apart from the fact that its response to mechanical deformation is very likely to be modified not only so far as the whole macula is concerned but especially perhaps regionally with the strong possibility of configurational changes fluctuating in time

It may now be useful *to investigate the chief* observations of unit behaviour in orbit in the light of these supposed changes in macula configuration

The fact that the first two hours and twenty-eight minutes of recording from the units in orbit were lost owing to transmission failure prevents *us from* knowing whether the immediate effect of the establishment of the free-fall condition was a lowering or a rise in unit *activity The now generally* accepted hypothesis in the interpretation of the mode of *functioning* of vestibular hair-cell receptors is *that they* respond chiefly if not exclusively to shearing forces tangential to the plane *of the* epithelium in which they are lodged *This hypothesis replaced earlier hypotheses* operating with the possible mechanism of changes in pressure or tension exerted on the hair processes of the receptor cell Recently *it was pointed out* however that changes *in* otolith pressure could be translated into changes *in* shearing force at the base of the hair processes *and thus be responsible for changes in unit* activity (Benson & Barnes, 1973) *If this be* so we would have to consider the possibility *in the* case of the present *experiments* that the unloading of the otolith membrane *may result* in significant changes in the spatial disposition *in the hair processes* in a shearing direction and may *therefore* be responsible for changes

vestibular units The absence of significant alterations in the action potential parameters appears to indicate that the basic impulse generating mechanism was unaffected by the free fall condition

These results seem to prove that the microelectrode technique in every way satisfied the requirements

The FOEP proved to be a perfect solution for maintaining physiological conditions in an animal under water It will provide a suitable tool for new experiments both in space and in the laboratory performed on fish or amphibians aquatic animals in which the environmental conditions are more easily controlled and monitored than in terrestrial ones However some inconveniences existed The water circulation system for instance introduced an unwanted artifact in the form of water pump vibration

WELFARE UNDER WATER

A frog can survive under water for several weeks provided the temperature is not raised above 14–15°C at a normal atmospheric PO_2 namely 155 mm of mercury (Serfaty & Gueut al 1943) In these conditions however the O_2 consumption is reduced to 20% of the normal value in air and survival is achieved only by the corresponding decrease of the metabolic rate (Leivestad 1960) This cannot therefore be considered completely satisfactory for normal metabolism The O_2 transport through the skin is due to passive diffusion only and therefore is bound to be proportional to the PO_2 of the environment (Krogh 1904 Dolk & Postma 1926) The thickness of the skin is such that a sizeable O gradient must exist between the environmental PO_2 and PO_2 of the blood in the capillary network Both in the air and in respiration under water most of the CO_2 if not all is eliminated through the skin whereas the O_2 in air respiration is absorbed partly from the skin at a constant level throughout the year and partly through the lungs with seasonal variation. (Jullien et al 1958 Bastert 1929)

It is obvious that the efficiency of the skin respiration depends on the surface/mass ratio of the animal the amount of O_2 provided being proportional to the surface and the amount of O_2 consumed during the metabolic activity to the mass. In the large bull frog the ratio is not particularly favourable As most of the O_2 is consumed by the muscles during exercise a partially paralyzed frog would need less O_2 than a fully active one

From what is stated above it can be concluded that the animal under water can survive only within rather narrow limits of temperature On the high side the frog incurs progressive asphyxia on the cold side the frog can stand even below freezing-point temperatures, but at 4–8°C the firing of the nerve fibre practically ceases

RESULTS

A gravity sensitive receptor or tonic statoreceptor is identified in the earth gravitational field by responding to a steady position of the head (or a steady linear acceleration) with a stationary mean firing rate after a more or less pronounced adaptation (Gualtierotti & Gerathewohl 1965 Vidal et al 1971) In the case of the present investigations no attempt was made to identify the origin of the activity recorded with respect to a specific otolith organ since in an orbital experiment post mortem examination is precluded by the fact that the preparation cannot be recovered However in this series of experiments units were selected whose highest sensitivity was to tilt in the sagittal plane This indirectly suggests that these units may have been controlled by the utriculus Any such localization must however remain extremely tentative since parts of the sacculus macula lie in a plane compatible with the responses

All data on the vestibular statoreceptor activity both at rest and during stimulation

far in the literature are limited to ort-periods of acute experiments & Roberts 1949 Rupert et al & Luschei 1971) There is no in- such activities observed for a long time to analyse the general cteristics of the firing rate of the nits for periods exceeding a possi- ycle During the present experi- pulse-train data of the same single urons of the vestibular stato- ve been recorded for the first time l-loop system over a number of periods of 24 hours up to 6 in the ntrolled environmental conditions r the FOEP

RESULTS

A gravity sensitive receptor or tonic statoreceptor is identified in the earth-gravitational field by responding to a steady position of the head (or a steady linear acceleration) with a stationary mean firing rate after a more or less pronounced adaptation (Gualtierotti & Gerathewohl 1965 Vidal et al 1971) In the case of the present investigations no attempt was made to identify the origin of the activity recorded with respect to a specific otolith organ since in an orbital experiment post-mortem examination is precluded by the fact that the preparation cannot be recovered However in this series of experiments units were selected whose highest sensitivity was to tilt in the sagittal plane This indirectly suggests that these units may have been controlled by the utriculus Any such localization must however remain extremely tentative since parts of the sacculus macula lie in a plane compatible with the responses

All data on the vestibular statoreceptor activity both at rest and during stimulation

tween these two types of response is now generally interpreted as a difference in the degree and speed of peripheral adaptation. There is at present no mental model available that could link the observed changes in orbit to any possible adaptive process in the sensory cell and its first-order neuron especially as such processes themselves are far from being understood

To sum up it appears reasonable for the present to confine oneself to the consideration of the mechanical circumstances and their possible influence on unit activity as discussed above

The question arises what if any relation the observed effects of "weightlessness" on the behaviour of single otolith-controlled vestibular units have on the orientation and wellbeing of the astronaut in orbit Although our primary concern are problems of vestibular physiology as such it appears desirable to ask whether our data can suggest possible causes of space sickness or orientational maladjustment It is obvious that an analysis of clinical syndromes would have to be based on rigorously designed and executed tests carried out on space personnel in an orbiting spacecraft, but we believe that the mismatch of information that could possibly be associated with the modification in response behaviour of the otolith-controlled units observed in this experiment as against the background of other non-gravitational sources of information could be expected to contribute in a specific manner to such syndromes

It could be argued that the number of units observed in orbit is too small to permit the drawing of significant conclusions about the organ s response to "weightlessness" Against this must be set the fact that the results reported here rest on seventy recordings per individual unit (twenty on the ground and fifty in orbit) carried out over a period of approx 180 hours (24 on the ground and 155 in orbit) We are therefore dealing with a situation in which individually identifiable units furnish us with controlled observations in an extended time dimension This is, in fact the first time that individual first-order vestibular units have been observed continuously for such prolonged periods of time in a chronic preparation of a physiologically near intact animal

Summary

The otolith-controlled activity at rest or under the influence of low-intensity vibratory stimulation and the responses to pre-programmed centrifuge spin cycles of single 1st-order axons of the vestibular nerve of the bull frog has been recorded for up to 7 days through extracellular microelectrodes in the 1 g earth gravitational field and in an orbital satellite (10^{-} – 10^{-} g max)

During the recording period 2 bull frogs, intact but for the partial paralysis of the 4 limbs, were kept under standard environmental conditions (PO temperature illumination, pressure acceleration) in a specially built experimental container completely filled with water in which the animals were submerged for the duration of the experiment The environmental variables indicated above and the ECGs were monitored continuously

The activity at rest in the 1 g gravitational field was irregular The coefficient of variation for the statoreceptor activity was found to be close to 1

In orbit a significantly larger fluctuation of the units activity in the absence of the preset stimulus (centrifuge cycle) was observed as well as a change of gain of the responses to the preset stimulus and to vibrations. One of the most striking effects of "weightlessness however was a reversible change in the mode of response to the preset stimulus from tonic to phasic and vice versa.

in the overall unit activity Changes in otolith pressure need not be expected to be uniform over the whole otolith membrane but could have a patchy distribution owing to the lack of stiffening caused by unloading and this may account for the lack in uniformity in unit behaviour in orbit

So far as the fluctuations in gain are concerned it appears to us that configurational changes in the membrane supporting a given unit may influence its gain by either increasing or decreasing the efficiency of the mechanical deformation by the stimulus (mechanical gain) Nothing worth while can be said at present about any possible influence of weightlessness on the gain of the mechano-electric transduction process This would involve synaptic and membrane-based processes in a way impossible to assess

It may be argued that the changes observed in free fall could be due to extravestibular influences first and foremost among these effects that reach the units via the efferent system innervating the hair-cell Although the functional role of the vestibular efferent system has not as yet been conclusively established in any organism there are certain assumptions which would be compatible with a fluctuation in unit activity in response either to its own activity level at any given moment or with that in extra vestibular systems such as stretch and joint receptors in neck and limbs integumental visceral and vascular receptors a s o

In the case of the present experiments we can to a large extent exclude the responsibility of visceral and vascular sources for changes in efference because the animal is completely immersed in water Moreover the nerve supply to the limbs was almost completely interrupted only a small proportion of the afference from the hind legs remaining intact The chief source of extra vestibular afference would therefore be confined to the head neck and intervertebral joints However the differential density of bone and soft tissues is without possible influence in free fall Any change in the inflow of efference into the vestibular organ could therefore only be random and such randomness might itself be a mediate consequence of receptor instability contributing to its total extent

In this connection it may be called for to deal with one possible criticism of our experimental procedure It may be asked why a control experiment was not performed in this mission based on the interruption of the efferent pathway either in one of the two frogs or in the second labyrinth of one of them In answer to this it must be categorically stated that the exclusion of the efference by proximally sectioning the eighth nerve or by central nervous lesions was out of the question because any interference with the blood circulation would nullify the value of the experiment not only by jeopardizing the prolonged survival of the animal but equally important by impairing the physiological condition of the end organ possibly also by initiating degenerative changes in the peripheral system during the period of the orbital experiment

The only possible way of interfering with the efference in a less traumatic manner would be the administration of a drug known to block the efferent synapse without affecting the afferent one This has recently moved into the realm of possibilities Not only has it become fairly certain that the afferent and efferent synapses conduct by means of different transmitter substances (Iurato et al 1971) but Flock & Russell (1973) have claimed to have succeeded in pharmacologically blocking the efferent synapse in the lateral line organ of the burbot (Lota lota) without affecting the basic transmission process in the afferent synapse apart from producing its disinhibition Such possibilities were not available at the time of the OFO A experiment here described but may open promising possibilities for any future experiment of this kind

One of the most striking effects observed in free fall was the reversible change from a tonic to a phasic mode of response to the centrifuge spin cycle and vice versa The difference be

Zusammenfassung

Die Aktionspotentiale einzelner Neurone I Ordnung des Otolithensystems von Ochsenfröschen wurden mit extrazellulären Mikroelektroden im Gravitationsfeld der Erde (1 g) und in einem Satelliten in einer Erdumlaufbahn ($10^{-4}-10^{-3}$ g max) abgeleitet. Zusätzlich wurden vorprogrammierte vestibuläre Reize nämlich niederfrequente Vibration und centrifugale Beschleunigung angewandt

Die zwei Ochsenfrösche wurden durch Nervendurchtrennung an den vier Extremitäten immobilisiert Die Umweltbedingungen (PO_2 Temperatur Beleuchtung Druck Beschleunigung) wurden durch Verwendung eines speziellen life support system in welchem die Tiere unter Wasser für die gesamte Dauer des Experimentes untergebracht werden möglichst konstant gehalten Die Aktionspotentiale im 8 Hirnnerven und das EKG wurden kontinuierlich registriert

Das Entladungsmuster im 1 g Schwerefeld war auffallend unregelmäßig Der Variationskoeffizient für die Statoreceptoren Aktivität lag im Bereich von 1

Im schwerelosen Orbitalflug war die Fluktuation des unitären Entladungsmusters schon im ungereizten Zustand signifikant größer als auf der Erde Außerdem wurde eine Änderung der Empfindlichkeit der Einheiten gegenüber dem vorgegebenen Beschleunigungsreiz und gegenüber Vibration festgestellt Der überraschendste Effekt der Schwerelosigkeit war aber die reversible Änderung in der Reaktion der Einheiten gegenüber einem vorgegebenen Reiz zwischen einer tonischen zu einer phasischen Reaktionsform und umgekehrt

Die Ergebnisse werden diskutiert hinsichtlich wahrscheinlicher mechanischer Änderungen *die durch Entlastung der Macula* im freien Fall eintreten und außerdem hinsichtlich möglicher Änderungen in der *efferenten Kontrolle der Macula* und im Hinblick auf adaptive Prozesse

Introduction

INCIDENCE

Aural barotrauma is a significant problem in otolaryngology. New cases of temporary and permanent hearing loss from barotrauma continue to be reported (1, 2, 3, 4, 5, 6, 7, 8). With more and more people engaged in recreational diving activities the number of cases is increasing. It has been estimated that five million people in the United States are utilizing SCUBA diving equipment (9). As early as 1944 a Naval study reported the incidence of aural barotrauma to be present in 5 to 20 per cent of all diving and flight operations (10). Aural barotrauma is not only encountered at high altitudes, great depths of water and long exposures to increased pressure, but can occur with recreational diving at shallow depths after short periods of time. Symptoms of aural barotrauma are usually seen in the first six to ten feet and are greatest at eleven to twenty feet of descent (9). It has been reported that most tympanic membranes will rupture at one-half atmosphere of pressure differential across the drum (1 atmosphere = 33 feet) (11).

DEFINITIONS

Aural barotrauma is the damage to the ear resulting from a difference between middle ear pressure and environmental pressure (12). Throughout the literature there is a broad mixture of terms relating to this entity, e.g., alternobaric trauma, hyperbaria, barotitis media, barotitis, inner ear barotrauma, otitic barotrauma, otic barotrauma, aero-otitis, salpingotympanitis, aviator's ear, caisson worker's deafness, caisson disease.

Often confused clinically with and sometimes indistinguishable from aural barotrauma in the otolaryngology literature is a different entity called decompression sickness ("bends"). This is ear pathology resulting from total body release of nitrogen bubbles into the cochlea's intravascular, endolymphatic or perilymphatic system, causing mechanical damage and tissue anoxia. The fact that this pathology is confused in the clinical and experimental literature is unfortunate and inappropriate. The etiology and pathology associated with aural barotrauma and decompression sickness indicate that these conditions should be viewed as separate entities. Moreover, an analysis of the mechanisms underlying aural barotrauma requires that we strictly define the associated changes with careful consideration for site and type of pathology. The literature on barotrauma may be examined under the broad categories of *middle ear barotrauma* and *inner ear barotrauma*. Experimental investigations on animals provide the means by which mechanisms underlying this pathology may be evaluated.

MIDDLE EAR BAROTRAUMA

Middle ear barotrauma is the most common medical disorder experienced by divers (12). It generally can be graded as to severity on otoscopic examination. The associated middle ear changes are time related (13) yet some can occur in the first five minutes (14). There is general agreement in previous reports on the stages of damage noted with increased pressure exposure (8, 12, 13, 14, 15, 16). They are as follows:

1. Retraction of the tympanic membrane.
2. Dilation of tympanic membrane blood vessels around the malleus and in pars flaccida.
3. Edema of the mucous membranes lining the middle ear space.

pressure conditions. Flisberg et al. (22, 23) applied negative pressure to the mastoid air cell system of human patients and observed a direct relationship of increasing pressure to the amount of clear fluid transudate present. Mc Cormick et al. (24) is the only available report which relates electrophysiological with morphological changes seen with experimental barotrauma. However in this study it is not possible to separate the effects of barotrauma from concomitant effects of decompression sickness.

PURPOSE

The purpose of the present investigation was to simulate aural barotrauma in an experimental animal model by introducing various longstanding pressures directly into the middle ear space of the guinea pig. Thereby electrophysiological responses of the cochlea and histopathological middle and inner ear changes could be examined, graded and an attempt made to relate them to each other.

Material and Methods

Thirty-eight young healthy random strain guinea pigs weighing 250 to 400 grams were used. All animals demonstrated a Preyer's reflex and a normal middle ear at the time of surgery. Electrophysiological data is based upon observations in thirty-five animals. Thirty animals were subjected to histopathological studies. The guinea pigs were divided into two experimental groups. Group I consisted of twenty animals subjected to a continuous sustained specified pressure for a 120-minute period. Group II consisted of eleven animals. They were also subjected to 120 minutes of sustained pressure except that the pressure was returned to zero every twenty minutes for brief electrophysiological readings and then promptly restored to the specified sustained pressure. Four animals were used as controls.

Animals were anesthetized with Methoxyflurane inhalation anesthesia, underwent a tracheostomy and were artificially respirated with a Palmer small animal respirator (25). Body temperature was monitored by a rectal probe and maintained at 36 C through a feed-back system coupled to a heating pad beneath the animal. An electronic heart monitor was in operation throughout each experiment to help assure the animal's physiological stability. The animal was placed in a head holder with an occipital screw and an anterior jaw clamp; these held the animal's head securely for experimental manipulation.

After a surgical plane of anesthesia was established and the animal determined to be physiologically stable, the bulla was exposed. The middle ear space was exposed by drilling a small hole in the bulla. The hole was widened until the round window was visualized and any small bone fragments that entered the middle ear space were removed. A platinum alloy ball electrode (0.007-inch diameter) coated with Insl-X was carefully placed on the round window membrane with the aid of a micromanipulator and cemented in position at the opening in the bulla with dental acrylic. A 23-gauge cannula with the tip just within the bulla was cemented in place adjacent to the electrode. Via this cannula middle ear pressure was varied directly. For animals in one group (Group II), a small inspection hole was left in the dental cement and occluded with clay during pressure exertion. This small inspection hole permitted visualization of the middle ear space and removal of fluid at the end of the experiment. In Group I, the bulla was closed completely with the dental cement.

All experiments were performed in a double-walled soundproof chamber with all anesthetic, sound-generating and recording equipment outside. Sound stimuli were presented to the animal

6 Rupture of the tympanic membrane with or without displacement of the ossicular chain.

Haines (16) performed audiometry on over 6 000 men before and after 50 lbs./sq in experimental test dives. He found little effect on hearing except when the middle ear contained serosanguinous fluid

INNER EAR BAROTRAUMA

While the interest in hearing impairment in divers has focused on the middle ear it was recently emphasized that inner ear hearing loss may also result from aural barotrauma. Inner ear barotrauma may also occur simultaneously with middle ear barotrauma often with spontaneous recovery (13) However Freeman and Edmonds (4) reported five patients with persistent sensorineural deafness of which only one had middle ear hemorrhage There are now numerous reports of permanent hearing loss from diving The exact etiology of these cases is often obscure due to the lack of confirmed pathology and also because of a lack of pre incident audiograms (4) Table I shows a compilation of suggested etiologies of inner ear barotrauma A few clinically and experimentally supported etiologies are included As can be seen, the only cases supported by clinical evidence include round window membrane rupture or an oval window fistula whereas, the experimental evidence indicates inner ear hemorrhages or blood component abnormalities of etiologic significance for inner ear barotrauma.

EXPERIMENTAL INVESTIGATIONS

Presently there is little experimental data published aiming at substantiating the many suggested theories of aural barotrauma. Some electrophysiological work has been done in cats and guinea pigs on the effects of static pressure on middle ear dynamics (17 18 19 20). These investigations show a correlation between increased negative and positive pressure, decreased output function and increased middle ear impedance. Miller (21) subjected cats with an open bulla to hyperbaric conditions in a diving chamber A subsequent loss of 15 to 20 dB was noted in the cochlear microphonic (CM) response while the animals were pressurized. Since the bulla was opened, however no differential pressure existed across the tympanic membrane and thus the experimental model did not duplicate the usual barotraumatic

pressure. For Group II animals the final measures were also taken after fluid buildup was removed from the middle ear space. Suction applied via a cotton wick to the round window area was used to remove any fluid.

Three animals in the study were excluded from the final electrophysiological results because of technical preparation errors. However these animals were evaluated morphologically.

Thirty animals were examined morphologically at the close of the experiment. They were inspected and graded with the operating microscope and changes noted in the tympanic membrane (perforations, distended vessels, hemorrhage, abnormal mobility) and the middle ear space (ossicular discontinuity, oval and round window abnormalities, middle ear mucosal changes, amount and appearance of fluid). Subsequently the vascular system of twenty two animals was perfused with a contrast solution by a transcardiac infusion technique (26, 27). Briefly, this method includes perfusion of the vasculature with Ringer's solution, and infusion of Prussian blue contrast solution. Both cochleas were assessed in the same way. Under the stereomicroscope, the middle ear was again evaluated with an open bulla. A careful puncture of the round window, removal of the stapes in order to open the oval window and a small hole at the cochlear apex were made. Subsequently either the cochlea was injected and/or immersed in 5% glutaraldehyde for 24 hours fixation. After fixation and decalcification (8% EDTA buffered with NaOH), a mid-modiolar longitudinal section of the cochlea was made. The sectioned surface was carefully evaluated under the stereomicroscope with particular emphasis on investigating the position of the vestibular membrane, the occurrence of hemorrhage and other major changes. Then the cochleas were counterstained in 0.5% osmic acid for eight minutes. The sectioned surface of the cochleas were carefully examined again under the stereomicroscope. After further dissection, to prepare the surface sections of the membranous labyrinth, the vasculature and the sensorineurepithelium as well as supporting structures and membranes of the external wall and spiral lamina were examined in light and phase contrast microscopy. Representative findings were documented with a photomicroscope.

ELECTROPHYSIOLOGICAL OBSERVATIONS

Effects on the one microvolt CM input–output functions and I_1

The basic cochlear electrophysiological results obtained from this study are illustrated in Fig. 2 through 5. Fig. 2 shows changes in the one microvolt CM contour at zero pressure after various negative pressures were applied for 120 minutes. The pressures range from −50 to −700 mm H_2O as noted. In general, except for the lowest frequencies examined, the response is reasonably flat across frequencies with an approximate 10 dB difference separating the animals run at −50 and −100 mm H_2O from the animals run at −200 to −400 mm H_2O. There is a difference in sensitivity of approximately 20 dB separating the −200 to −400 mm H_2O group from the −500 to −700 mm H_2O

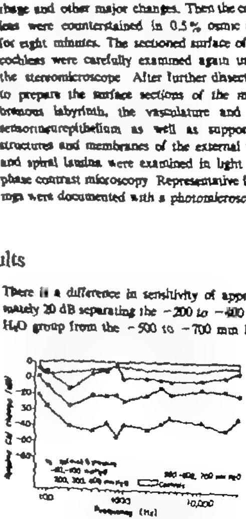

Fig. 2. Mean 1 μV CM difference scores at 0 pressure after 120 minutes with sustained negative pressure (Group I animals).

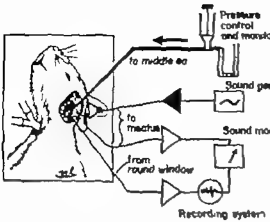

Fig 1 Diagram of experimental design for present electrophysiological experiments.

as either pure tones or clicks via a sound cannula positioned tightly against the external auditory canal. The basic experimental setup is diagrammed in Figure 1 Pure tones used to produce the one microvolt CM were generated by a wave analyzer (General Radio Type 1900-A), amplified by a MacIntosh (Model 240) amplifier attenuated by two attenuators (Daven Type T-690-CR), and presented to the animal via a PDR 600 speaker Thirteen pure tone frequencies ranging from 80 to 30 000 Hz were employed All sound intensities in this report are recorded in dB re 0 0002 dynes/cm² and were determined by a Brüel and Kjaer 1 mm probe tube and condensor microphone positioned inside the sound cannula 2 mm from the tympanic membrane

Click stimuli used to evoke the N_1 action potential were produced by a Type 162 waveform generator and Type 161 pulse generator (Tektronix, Inc) and were likewise presented to the animal through the PDR 600 speaker The clicks were 0 1 msec in duration and were produced at a rate of 10 per second

Both the one microvolt CM and the N_1 action potential data were recorded from the round window electrode after being amplified 1 000 times by a P 5 series Grass differential amplifier Input to the amplifier was via a high impedance probe Both the dynamic range and the one microvolt CM were measured with the wave analyzer (General Radio Type 1900-A) tuned to a 3 Hz bandwidth. N_1 data was recorded as the amount of attenuation (dB) necessary to produce a 200 microvolt peak to-peak N_1 action potential as it appeared on an oscilloscope screen (Tektronix Type 565 dual-beam).

The guinea pigs subjected to 120 minutes of a specified pressure (Fairchild Hiller-Stratos vacuum regulator Model 15). The regulator was arranged as a constant pressure device so that a specified pressure could be maintained in the presence of Eustachian tube function or small tympanic membrane perforations. Pressure values ranged from +400 to +600 mm H_2O and − 50 to −1 000 mm H_2O

Eleven animals from Group I (continuous sustained pressures) underwent a brief initial static pressure run at five frequencies (80 to 4 000 Hz) for pressures +300 to −300 mm H_2O During this test, the one microvolt CM was recorded at eight graduated pressures These pressures were randomly presented and maintained only for brief (≈ 15 sec) periods of time. Seven additional animals underwent a similar static pressure change after 120 minutes of high sustained pressure exposures (±500 to 550 mm H_2O). The functions relating CM response to static middle ear pressure were compared in these two groups tested before and after the pressure exposure.

Four animals served as controls. Three of these control animals underwent the same surgical procedures as Group I and Group II animals except that no pressure was applied A fourth control animal was used to examine the effects of a small linear perforation created in the posterior aspect of the tympanic membrane

Electrophysiological readings were taken prior to pressure application and after the onset of applied pressure. The one microvolt CM and N_1 responses were then recorded every twenty minutes At theses times, the one microvolt CM was recorded for six frequencies (80 to 10 000 Hz) For Group II animals, additional readings were taken every twenty minutes at zero pressure At the end of the 120-minute pressure application, electrophysiological measures were repeated in all animals at zero

pressure. For Group II animals the final measures were also taken after fluid buildup was removed from the middle ear space. Suction applied via a cotton wick to the round window area was used to remove any fluid.

Three animals in the study were excluded from the final electrophysiological results because of technical preparation errors. However these animals were evaluated morphologically.

Thirty animals were examined morphologically at the close of the experiment. They were inspected and graded with the operating microscope and changes noted in the tympanic membrane (perforations, distended vessels, hemorrhage, abnormal mobility) and the middle ear space (ossicular discontinuity, oval and round window abnormalities, middle ear mucosal changes, amount and appearance of fluid). Subsequently the vascular system of twenty-two animals was perfused with a contrast solution by a transcardiac infusion technique (26, 27). Briefly this method includes perfusion of the vasculature with Ringer's solution, and infusion of Prussian blue contrast solution. Both cochleas were assessed in the same way. tive pressure, a graduated decrease in cochlear output occurs and appears as a parallel shift in sensitivity. Similar observations were made in other animals at different negative pressures.

Development of electrophysiological effects

Figs. 6 through 9 show the time course development of the electrophysiological results presented in Figs. 2 through 4. In Fig. 6, the change in the one microvolt CM at 400 Hz with various negative pressures ranging from −50 to −700 mm H_2O over a two hour period is demonstrated. In general, there is a graduated progressive loss in sensitivity with time. This same basic change was noted in other frequencies tested, but the response at 4 000 Hz was more variable.

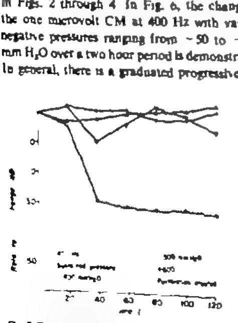

Fig. 7. Time course changes in the 1 μV CM for individual animals (Group I) subjected to 120 minutes of sustained positive pressure.

Fig. 7 demonstrates the change in the one microvolt CM at 400 Hz with time for positive pressure animals ranging from +400 to +600 mm H_2O. Except for the animal run at +600 mm H_2O there was no change in response. This latter animal had a perforated tympanic membrane by the end of the experiment. From the data in this figure it is tempting to suggest that this perforation occurred between 20 and 40 minutes following pressure onset. However the absence of any major effect of perforation alone (black triangle) makes this suggestion difficult.

Time course development for N_1 data is demonstrated in Figure 8. As with the CM data (in Fig. 6) there also is a decrease in sensitivity with time and increasing pressure. Animals run at other negative pressures (not shown in Fig. 8) fit in an orderly sequential manner based on their respective pressures.

The time course development of the CM and N_1 effects is not due to applied pressure alone. This is demonstrated in Fig. 9. This figure summarizes the mean changes in the one microvolt CM at zero pressure readings over time in seven animals from Group II. This data demonstrates a graduated decrease in sensitivity in the first forty minutes with animals subjected to various pressures. Thereafter the course plateaus

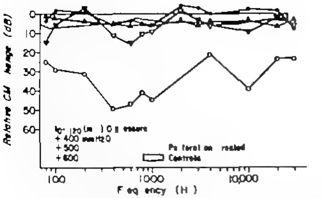

Fig 3 One μV CM difference scores at 0 pressure after 120 minutes of sustained positive pressure (individual Group I animals)

group Among these three groups of animals, there is a tendency for the higher pressures to have the greater effect on the mid and high frequencies The data was obtained from animals in Group I but the same relationship was observed in Group II animals

Fig 3 demonstrates the change in the one microvolt CM sensitivity following two hours of applied positive pressure (+400 to +600 mm H_2O) It is to be noted that the animal run at +600 mm H_2O developed a perforated tympanic membrane and had a loss as great as 50 dB at 400 Hz. A similar one microvolt CM contour was obtained for high negative perforating pressures as well In Fig. 3 the +600 mm H_2O animal may be compared to the control animal (no pressure applied) in which a perforation was created in the posterior aspect of the tympanic membrane Except for the

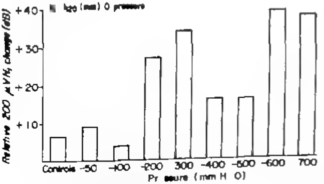

Fig 4 200 μV N difference scores at 0 pressure after 120 minutes of sustained negative pressure (individual Group I animals).

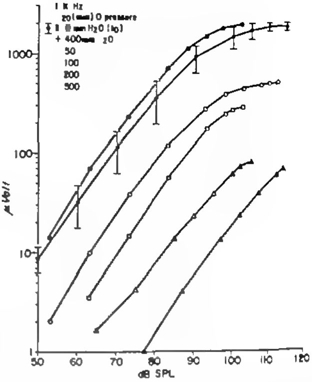

Fig 5 Input-output function at 0 pressure after 120 minutes of sustained pressure. Individual animals from Group II are compared to an initial mean curve at 0 pressure (two standard deviations are shown).

animals examined at pressures sufficiently high to cause drum membrane rupture the effect of positive pressure exposure was insignificant.

The N_1 data at zero pressure after 120 minutes of negative pressure exposure from −50 to −700 mm H_2O is shown in Fig. 4 Each bar represents individual animals from Group I There is a gradual decrease in sensitivity from −50 to −300 mm H_2O beyond which sensitivity either plateaus or becomes variable While this graph demonstrates individual Group I animals only similar results were noted in Group II animals as well

The input–output dynamic range at 1 000 Hz for one positive pressure animal and for four negative pressure animals is demonstrated in Fig. 5 The configuration of this input-output curve is similar for other frequencies tested as well. The negative pressure animals are in contrast to the animal run at +400 mm H_2O There is a definite decrease in sensitivity with increased negative pressure With greater nega

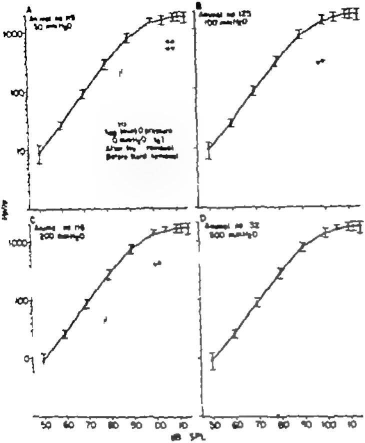

Fig. 11. Composite input-output functions at 0 pressure after 120 minutes of sustained pressure. Individual animals from Group II are shown before and after fluid removal.

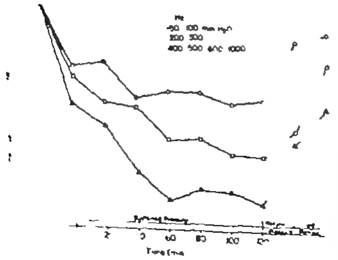

Fig. 12. Mean time course changes in the *1 μV CM* with sustained pressure for 120 minutes. Pressure is returned to 0 mm H_2O and fluid removed at the end. Time $\overline{T_0}$ and 0 mm H_2O is the reference (Group II animals).

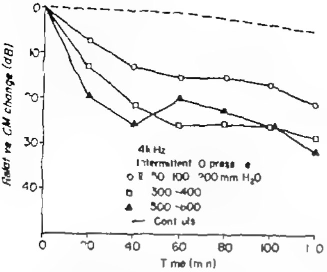

Fig 9 Mean time course changes in 0 pressure readings for the 1 μV CM during a 120 minute period of sustained negative pressure (Group II animals).

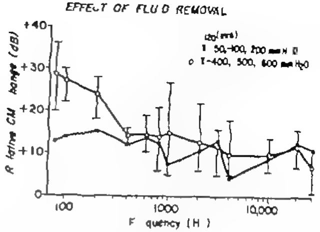

Fig 10 Mean improvement in the 1 μV CM resulting from fluid removal after 120 minutes of sustained negative pressure. The range as well as the mean is shown for the higher pressure group

or is somewhat more variable In all frequencies tested −50 and −500 mm H_2O formed the two extremes at the end of 120 minutes Other pressures[1] followed an intermediate course usually related to applied pressure, but an overlay of functions was noted[1]

Effect of fluid removal

Serous fluid and/or blood were noted in the middle ear of animals subjected to negative pressures When this fluid was removed at the end of each experiment (Group II animals) there was an overall improvement in the one microvolt CM of approximately 20 dB in the low frequencies 15 dB in the mid frequencies and 10 dB in the high frequencies. Furthermore as is shown in Figure 10 there is a difference in the mean improvement for the low frequencies (80 to 200 Hz) in animals run at pressures of −50 to −200 mm H_2O and the group of animals run at −400 to −600 mm H_2O For higher frequencies there does not appear to be a significant difference between these two groups

Effects of fluid removal on the dynamic range of the CM for Group II animals is shown in Fig 11 This composite figure of Group II animals includes data on individual subjects exposed to pressures of −50 to −500 mm H_2O The input-output function before and after fluid removal at 1 000 Hz is shown As can be seen from these graphs, there is a progressively greater effect from fluid as the pressure is increased up to −500 mm H_2O At −500 mm H_2O pressure, the effect of fluid removal is not much greater than that at −100 mm H_2O

At the end of each 120 minute pressure exposure an improvement in the one microvolt CM and N_1 response was seen when the system was returned to zero pressure and an additional improvement was noted when any existing fluid was removed These two findings are summarized in Fig. 12 for the one microvolt CM at 1 000 Hz over time This data is based upon observations in Group II animals The improvement in the CM for the animals tested between −50 and −100 mm H_2O is within 10 dB of normal while for the animals run at −200 to −300 mm H_2O the recovery was within 20 dB In the group with pressures above this level the recovery averaged 35 dB

Response to static pressure changes

Under constant stimulus conditions, the CM changes with different middle ear pressure The form of the CM change in normal guinea pigs is shown by the dashed line in Fig 13 This figure shows the changes in sound intensity

[1] Fig. 9 is based upon mean changes rather than individual observations due to the amount of individual variability which made the presentation of representative examples inappropriate

HISTOPATHOLOGICAL OBSERVATIONS

General

The contrast injections were less successful than in previous studies where the middle ear had been opened and electrophysiological measurements and/or surgery performed on the cochlea but without any induced middle ear pressure changes (30 31 32). The most common finding was in fact an uninjected middle ear mucosa and a cochlea with contrast in only some modiolus vessels. In some cochleas, the blood was washed out by the saline perfusion, but no contrast had entered the vessels. In still others, the contrast filling was good in the middle ear mucosa and in the cochlear basal turn, with deficient vessel contrast apically. The outcome of the contrast injections appeared to be related to the type and magnitude of pressure. In animals which were assessed with positive and low negative pressures, the contrast injection was more successful than in those animals which were subjected to high negative pressures. The contralateral ears in general (18/22) showed the same amount of injected contrast as the experimental ear. In three cases, the contralateral ear was more contrast injected than the experimental ear and in one animal the opposite was found. On the whole, the middle ear changes were more consistent and more easily observed than the discrete cochlear morphological findings.

Middle ear

The middle ear was examined for histopathological changes in thirty animals, distributed as demonstrated in Table II.

The *tympanic membrane* was *distended* in two of the positive pressure animals, in one of the low negative pressure animals and in all but two of all other negative pressure animals after two hours sustained pressure. In one animal from the pronounced negative pressure group where the drum membrane did not rupture, there was intra tympanic membrane hemorrhage as well as drum distention. The tympanic membrane was found to be *ruptured*

Table II *Present material. Histopathological examinations*

Middle Ear	Cochlea
Positive pressure	
5	4
Negative pressure (mm H_2O)	
Low (−50 to −100)	
4	2

in three of the five positive pressure animals, in one of the high negative and in two of the pronounced negative pressure groups. *Vessel distention* along the malleus was found in almost all animals (24 of 25 negative and 4 of 5 positive pressure animals) (Fig. 15). It thus appeared that most positive and negative middle ear pressures caused drum membrane distention and vessel dilation, and tympanic membrane rupture was related to the degree of pressure alone.

In three of five positive pressure animals and all negative pressure animals, the *middle ear* space contained serous fluid and/or hemorrhage. The middle ear contained *serous fluid* in two of the positive pressure animals, in all of the low and moderate negative pressure animals, and approximately half of the high negative pressure animals (8/15). *Hemorrhage* in the middle ear space was found in only two positive pressure animals but in most of the negative pressure animals (18/25) with greater frequency as the amount of applied negative pressure increased (Fig. 16). *Distention of middle ear mucosa vessels* was found in one of the positive pressure animals and in most of the negative pressure animals (22/25) (Figs. 16, 17). *Effusion of blood* around the vessel wall was found in 2 of 6 from the moderate negative pressure group in 4 of 12 animals in the high negative pressure group and in 2 of 3 animals from the

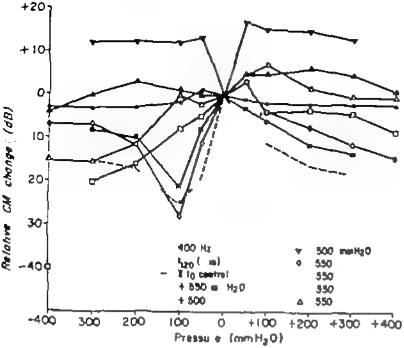

Fig. 13. Comparison of the mean initial 1 μV CM response at time T with static pressure changes to the same responses after 120 minutes of high sustained pressure (individual animals from Group I).

for a 400 Hz tone necessary to hold CM amplitude constant (at one microvolt) as middle ear pressure was changed. As middle ear pressure is varied from zero intensity of the sound must be increased.[1] These data were obtained in animals prior to exposure to a longterm middle ear pressure change. Following 120 minutes pressure exposure of ± 500 to ± 550 mm H_2O the response of the system to static middle ear pressure changes (solid lines in Fig. 13). Following a two-hour exposure, the system responds to middle ear pressure change from levels similar to the pre-exposure response to the extreme where changes in middle ear pressure actually increase the response of the cochlea to sound. The effect was not correlated with direction of pressure change or fluid buildup in the middle ear space. It did appear correlated to drum membrane flaccidity.

Fig. 14 shows the change in the one microvolt CM for zero pressure following a 120 minute period of sustained pressure. In addition these results are compared with three locations of intracochlear bleeding in nine animals. The animals used in this figure were from both Group I (four animals) and Group II (five animals). Average pressure variations were -500 mm H_2O and -630 mm H_2O. A 20 dB difference across frequencies between those animals with scala tympani hemorrhage and the animals with both scala tympani and scala vestibuli hemorrhage was noted. With scala vestibuli alone an intermediate decrease in CM sensitivity was observed.

[1] These data agree approximately with those reported in the literature by Wever et al (18, 28, 29).

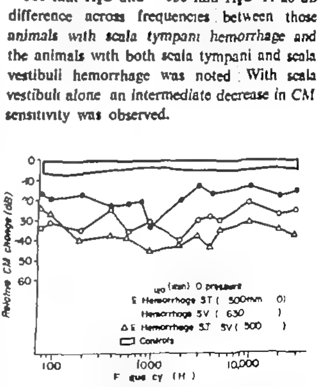

Fig. 14. Mean 1 μV CM difference scores at 0 pressure after 120 minutes of sustained pressures for groups of animals with scala tympani (ST), scala vestibuli (SV) and both scala tympani and scala vestibuli (ST SV) hemorrhages respectively. Four animals from Group I and five from Group II.

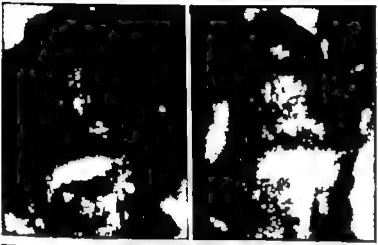
15



16

17

pronounced *negative middle* ear pressure group (Figs. 16, 17) *Engorgement of bone vessels* with blood was found in two of the positive animals and in 4 of 15 animals exposed to negative pressure greater than -500 mm H_2O (Figs. 16 and 18)

It thus appears that *positive pressure* influences the middle ear mucosa with only occasional transudation of serous fluid and hemorrhage as well as bone vessel engorgement With *negative pressure* a regular finding is transudation of serous fluid as well as distended middle ear mucosal vessels With more pronounced negative pressure blood can also be found surrounding the vessel wall as well as free hemorrhage in the middle ear space. In no case was any luxation or displacement of middle ear ossicles observed

Cochlea

Histopathological studies of the *inner* ear were made in one control animal (created tympanic membrane perforation) and 21 animals distributed as demonstrated in Table II *The round and oval window membranes* were found to be *intact in all animals* Similarly in no case were any histopathological changes demonstrated in the *Organ of Corti* or in the *endolymph* Contrarily *hemorrhage in perilymph* was the most distinctive pathological inner ear finding (Fig. 19) *Hemorrhage was found in all animals* except those in which the tympanic membrane ruptured and in two animals in the low negative pressure group Of those in the positive pressure group one demonstrated a discrete hemorrhage in both scala vestibuli and scala tympani of the basal turn. In another animal a more pronounced hemorrhage was found in the apical turn in scala vestibuli, decreasing basally In this animal there was also found a scala tympani hemorrhage in the second turn Two positive pressure animals without cochlear hemorrhage had ruptured *tympanic membranes*. In three moderate negative pressure animals one animal exhibited a small hemorrhage most apparent in the basal turn close to the round window in the scala tympani (Fig. 20), another showed hemorrhage in the scala vestibuli in the first and third turn, and the third had hemorrhage in both scala vestibuli and scala tympani in the basal and second turns.

In the high negative pressure group hemorrhage in the perilymph was found in eight animals. In three cases a pronounced hemorrhage was found in the scale tympani close to the round window In two animals, a discrete hemorrhage was found in the scala vestibuli, in one of them in the basal turn, another in the third turn. In three animals hemorrhage was found in both scala vestibuli and scala tympani In two of those it was limited to the basal turn and in the third animal most pronounced apically and decreasing basally One of the animals in the pronounced negative pressure group showed hemorrhage in the scala vestibuli of the basal turn.

Hemorrhage was never found in the cochleas with a ruptured tympanic membrane. Only in one case could the hemorrhage be related to a ruptured vessel In one animal (-400 mm H_2O) the "suspension vein" going from the modiolus in the basal turn close to the round window and running free through perilymph to the external wall, was found to be ruptured with hemorrhage. Interestingly in the same animal the control ear showed a similar hemorrhage and a ruptured suspension vein"

Granulated material appearing as debris rather than protein casts was found in three animals,

Fig 15 Tympanic membrane of a control animal (left) and after 120 minutes of sustained negative pressure (right). Vessel distention is easily observed along the malleus.

Fig 16 Guinea pig cochlea after 120 minutes of sustained negative pressure -200 mm H_2O (left) and -50 mm H_2O (right). The middle ear mucosa shows vessel distention and hemorrhage (left) whereas the bone vessels appear engorged with blood (right).

Fig 17 Guinea pig cochlea after 120 minutes of sustained negative pressure ($-1\,000$ mm H_2O). The contralateral ear (left) shows normal ingestion of contrast in middle ear mucosa vessels covering the cochlea. Fig 16 Guinea pig cochlea after 120 minutes of sustained negative pressure, −200 mm H_2O (left) and −50 mm H_2O (right). The middle ear mucosa shows vessel distention and hemorrhage (left) whereas the bone vessels appear engorged with blood (right).

Fig 17 Guinea pig cochlea after 120 minutes of sustained negative pressure (−1 000 mm H_2O). The contralateral ear (left) shows normal ingestion of contrast i middle ear mucosa vessels covering the cochlea No contrast has entered the vessels i the pressurized middle ear vessels (right) which appear dilated, engorged by blood and with hemorrhage in the middle ear space.

Fig. 13. Guinea pig cochlea after 120 minutes of sustained negative pressure (−500 mm H_2O). Vessels in the bone surrounding the cochlea appear somewhat dilated and engorged with blood.

two in the high negative pressure group and one in the pronounced high negative pressure group. In all cases the debris was located in the scala tympani close to the round window and found in addition to hemorrhage.

Small *bubbles* formed in the perilymph of the scala tympani were found in one positive and one negative pressure animal. *Distortion (or collapse) of the vestibular membrane* was found in one of the positive pressure animals, in two low negative pressure animals, in six of twelve animals in the high negative pressure group and in both animals in the pronounced negative pressure group (Figs. 18, 21). In general the distention or collapse was found throughout the cochlea.

Common findings in all groups were *pigment anomalies in the stria vascularis* with uneven distribution of pigment often markedly distributed around the vessel walls.

Other pathological findings included a few cases in which the surface cells of the stria vascularis appeared degenerated. In these preparations many vessels were completely uninjected and many were missing. In most of these cases of strial degeneration, similar findings were made in the control ear. Further, in addition to the stria vascularis changes, an increased number of *phagocytes (melanocytes)* was often found located along the vessel(s) of the spiral prominence. In a single animal from the low negative middle ear pressure group some injected contrast was found outside the collecting venules of the scala tympani. However a similar finding was made in the control ear in three different locations. Further this animal showed the most pronounced apical stria atrophy of all animals.

In conclusion, in all animals (except the low negative pressure animals) in which the tympanic membrane did not rupture, hemorrhage was found in the inner ear. In two animals hemorrhages were demonstrated bilaterally. The blood was most commonly demonstrated in the scala

Fig. 20. Guinea pig cochlea after 120 minutes of sustained pressure (400 mm H_2O). The most common site of hemorrhage (arrow) was in the scala tympani (ST) close to the round window. Spiral ganglion = SGn.

Control animal

Morphological experiences from several hundred guinea pigs served as controls for this project. The surgical procedure for these animals was described above. All animals showed a small amount of serous fluid in the middle ear. In the animal with a surgically created perforation the middle ear showed distended vessels in the mucosa and a small hemorrhage. The cochlea was well injected by contrast in the two basal turns. There was some debris inside the round window and some pigment anomaly of the stria vascularis.

In all animals, the contralateral unassessed ear served as a control. The examination was made in a similar fashion as in the experimental ear. Frequent findings were distention and collapse of the vestibular membrane, pigment anomalies of the stria vascularis, and an increased amount of melanocytes in the spiral prominence.

Fig 19 Guinea pig cochlea after 120 minutes of sustained negative pressure (−400 mm H_2O). *Localized hemorrhage* is seen in the scala tympani of the basal turn close to the modiolus. Considerable distention of the vestibular membrane is also observed.

tympani of the basal turn close to the round window often appearing to be sealed and situated at the modiolus wall *In some other* cases the hemorrhage was more diffuse and most prominent at the external wall. The hemorrhage often appeared to be adjacent to the opening of the cochlear aqueduct In four cases an accumulation of cellular white colored material was demonstrated (debris?) always situated in the scala tympani close to the round window *In three of these cases hemorrhage* was also found in the perilymph of the same ear The origin of the hemorrhage could in one case be related to the "suspension vein" which was broken and surrounded by an accumulation of red blood corpuscles In most ears with perilymphatic hemorrhages the "suspension vein if pres nt was intact

In no case was any rupture of the round window membrane, any hemorrhage in the endolymph, or any changes in the Organ of Corti observed In no case with tympanic membrane perforation was any cochlear hemorrhage demonstrated

Common findings were distended and collapsed parts of the vestibular membrane and a *nicking and splitting up of the peripheral parts* of the basilar membrane (Fig 21). However such findings were also made in the contralateral ear There was no difference in the morphological findings of the middle ear and cochlea in animals from Groups I and II

change in the one microvolt CM contour N_1 response and CM dynamic range. When middle ear hemorrhage was present, not only was there a large effect on cochlear potentials, but failure to improve following fluid and blood removal was also noted. This observation agrees with the clinical finding that hearing loss in middle ear barotrauma is frequently not noted until hemorrhage is present (16).

Changes in elastic properties of the tympanic membrane and the middle ear transmission mechanism were apparent, although not quantitatively measured in this study. With higher pressures, distention and hypermobility of the tympanic membrane were seen, reflecting a change in tympanic membrane elastic properties. In addition, the decreasing cochlear output recorded over time with zero pressure readings as well as with sustained pressure readings suggest that changes in elastic properties of the middle ear have occurred. We suggest this conclusion is further indicated by the observations made in Fig. 13 in which the response of the system following pressure exposure was markedly affected. This data indicates that in some instances middle ear pressure exposure may change the elastic characteristics of the drum sufficiently to actually reduce its effective surface area in receiving sound energy. However when positive or negative middle ear pressure is then reapplied to such a traumatized tympanic membrane its effective vibrating surface is restored with resultant improvement of the cochlear output.

The exact extent to which tympanic membrane perforations contribute to cochlear output change in our animal model is not clear. As noted in Fig. 3, a decrease in sensitivity of 30 dB in the one microvolt CM was found in the low and mid frequencies for a high positive pressure animal in which a tympanic membrane perforation was present. The results shown in Fig. 7 may be interpreted to indicate that this pressure induced perforation caused a sudden change in the recorded cochlear potential. Similar losses in the cochlear potential were also observed for high negative pressure animals with tympanic membrane perforations and with middle ear fluid. A loss of 30 dB in cochlear output is more than has been reported in human patients sustaining barotraumatic perforations, where losses on the order of 5 to 15 dB are observed (16, 33). These smaller losses agree somewhat more closely with that of one control animal in which a perforation was surgically made in the drum membrane and no fluid demonstrated. Consequently, we suggest that larger loss may in part be due to middle ear hemorrhage or fluid in addition to the perforation. Using a similar guinea pig model, we found only 30 dB loss across frequencies with tympanic membrane perforations caused by abrupt phasic pressure changes (from +1 000 to +5 000 mm H_2O) where fluid accumulation was not seen.

Interpretation of the relationship between inner ear hemorrhage and decreased cochlear function is not clear because cochlear changes take place simultaneously with middle ear histopathological changes. Also by using round window electrode recordings, it is not possible to localize the effects of discrete cochlear lesions accurately. Nevertheless, when the areas of intracochlear hemorrhage were compared there was a marked difference in the one microvolt CM response when hemorrhage was present in both scala tympani and scala vestibuli as compared to hemorrhage in scala tympani or scala vestibuli alone.

HISTOPATHOLOGICAL ASPECTS

In general, histopathological middle ear changes were consistent with previous findings in middle ears subjected to aural barotrauma (8, 12, 13, 14, 15, 16). The most important and conclusive findings of this investigation were the normal appearance of the round window, endolymph, Organ of Corti, and the high frequency of perilymphatic hemorrhages. The demonstration of round window membrane ruptures or oval window fistulas in the human ear under diving conditions (5, 35, 36, 37) could not be confirmed under the present experimental conditions. This may be due to a species difference in the

Fig 21 Guinea pig cochlea after 120 minutes of sustained negative pressure. There is pronounced distention of the vestibular membrane. The basilar membrane appears nicked in the basal direction. Other structures appear normal.

Discussion

ELECTROPHYSIOLOGICAL ASPECTS

Changes in cochlear electrophysiological responses were noted to be both time and pressure related In general there was a gradual decrease in the one microvolt CM and N_1 functions with time These changes were observed to be directly related to increasing pressure Little difference between those animals subjected to 120 minutes of sustained pressure (Group I) and those with interrupted zero pressure readings (Group II) was observed This indicates that the dynamic changes in pressure in Group II cannot account for the electrophysiological findings of this study Instead the functional changes are the result of the sustained middle ear pressure, and dependent both upon duration and amplitude.

The physiological changes were clearly related to fluid accumulation in the middle ear However with increasing pressure other factors may contribute to the greater loss of cochlear response e g changes in the elastic properties of the tympanic membrane, middle ear transmission mechanism, tympanic membrane perforations, and the presence of middle and inner ear hemorrhage.

As expected, middle ear fluid and hemorrhage were predominant in negative pressure animals and the amount and occurrence correlated with the degree of pressure applied The observation that fluid influences the ossicular chain (12, 16, 33) was substantiated by the present investigation. The effects of fluid removal are greater for the lower frequencies where middle ear mechanisms play a major role in sound transmission

In general, the higher negative pressure animals demonstrated a greater amount of middle ear hemorrhage than the lower pressure animals. Such animals exhibited the greatest

change in the one microvolt CM contour N_1 response and CM dynamic range. When middle ear hemorrhage was present, not only was there a large effect on cochlear potentials, but failure to improve following fluid and blood removal was also noted. This observation agrees with the clinical finding that hearing loss in middle ear barotrauma is frequently not noted until hemorrhage is present (16).

Changes in elastic properties of the tympanic membrane and the middle ear transmission mechanism were apparent although not quantitatively measured in this study. With higher pressures, distention and hypermobility of the tympanic membrane were seen, reflecting a change in tympanic membrane elastic properties. In addition, the decreasing cochlear output recorded over time with zero pressure readings as well as with sustained pressure readings suggest that changes in elastic properties of the middle ear have occurred. We suggest this conclusion is further indicated by the observations made in Fig. 13 in which the response of the system following pressure exposure was markedly affected. This data indicates that in some instances middle ear pressure exposure may change the elastic characteristics of the drum sufficiently to actually reduce its effective surface area in receiving sound energy. However when positive or negative middle ear pressure is then reapplied to such a traumatized tympanic membrane, its effective vibrating surface is restored with resultant improvement of the cochlear output.

The exact extent to which tympanic membrane perforations contribute to cochlear output change in our animal model is not clear. As noted in Fig. 3, a decrease in sensitivity of 50 dB in the one microvolt CM was found in the low and mid frequencies for a high positive pressure animal in which a tympanic membrane perforation was present. The results shown in Fig. 7 may be interpreted to indicate that this pressure induced perforation caused a sudden change in the recorded cochlear potential. Similar losses in the cochlear potential were also observed for high negative pressure animals with tympanic membrane perforations and with middle ear fluid. A loss of 50 dB in cochlear output is more than has been reported in human patients sustaining barotraumatic perforations, where losses on the order of 5 to 15 dB are observed (16, 33). These smaller losses agree somewhat more closely with that of one control animal in which a perforation was surgically made in the drum membrane and no fluid demonstrated. Consequently, we suggest that larger loss may in part be due to middle ear hemorrhage or fluid in addition to the perforation. Using a similar guinea pig model, we found only 30 dB loss across frequencies with tympanic membrane perforations caused by abrupt phasic pressure changes (from +1 000 to +5 000 mm H_2O) where fluid accumulation was not seen.

Interpretation of the relationship between inner ear hemorrhage and decreased cochlear function is not clear because cochlear changes take place simultaneously with middle ear histopathological changes. Also, by using round window electrode recordings, it is not possible to localize the effects of discrete cochlear lesions accurately. Nevertheless, when the areas of intracochlear hemorrhage were compared there was a marked difference in the one *microvolt* CM response when hemorrhage was present in both scala tympani and scala vestibuli as compared to hemorrhage in scala tympani or scala vestibuli alone.

HISTOPATHOLOGICAL ASPECTS

In general, histopathological middle ear changes were consistent with previous findings in middle ears subjected to aural barotrauma (8, 12, 13, 14, 15, 16). The most important and conclusive findings of this investigation were the normal appearance of the round window, endolymph, Organ of Corti, and the high frequency of perilymphatic hemorrhages. The demonstration of round window membrane ruptures or oval window fistulas in the human ear under diving conditions (5, 35, 36, 37) could not be confirmed under the present experimental conditions. This may be due to a species difference in the

Fig 21 Guinea pig cochlea after 120 minutes of sustained negative pressure. There is pronounced distention of the vestibular membrane The basilar membrane appears nicked in the basal direction Other structures appear normal.

Discussion

ELECTROPHYSIOLOGICAL ASPECTS

Changes in cochlear electrophysiological responses were noted to be both time and pressure related. In general, there was a gradual decrease in the one microvolt CM and N_1 functions with time These changes were observed to be directly related to increasing pressure. Little difference between those animals subjected to 120 minutes of sustained pressure (Group I) and those with interrupted zero pressure readings (Group II) was observed This indicates that the dynamic changes in pressure in Group II cannot account for the electrophysiological findings of this study Instead the functional changes are the result of the sustained middle ear pressure and dependent both upon duration and amplitude.

The physiological changes were clearly related to fluid accumulation in the middle ear However with increasing pressure other factors may contribute to the greater loss of cochlear response, e.g., changes in the elastic properties of the tympanic membrane, middle ear transmission mechanism tympanic membrane perforations, and the presence of middle and inner ear hemorrhage

As expected, middle ear fluid and hemorrhage were predominant in negative pressure animals and the amount and occurrence correlated with the degree of pressure applied The observation that fluid influences the ossicular chain (12, 16 33) was substantiated by the present investigation The effects of fluid removal are greater for the lower frequencies where middle ear mechanisms play a major role in sound transmission

Discussion

ELECTROPHYSIOLOGICAL ASPECTS

Changes in cochlear electrophysiological responses were noted to be both time and pressure related. In general, there was a gradual decrease in the one microvolt CM and N_1 functions with time These changes were observed to be directly related to increasing pressure. Little difference between those animals subjected to 120 minutes of sustained pressure (Group I) and those with interrupted zero pressure readings (Group II) was observed This indicates that the dynamic changes in pressure in Group II cannot account for the electrophysiological findings of this study Instead the functional changes are the result of the sustained middle ear pressure, and dependent both upon duration and amplitude.

The physiological changes were clearly related to fluid accumulation in the middle ear How ever with increasing pressure other factors may contribute to the greater loss of cochlear response, e.g., changes in the elastic properties of the tympanic membrane middle ear transmission mechanism, tympanic membrane perforations, and the presence of middle and inner ear hemorrhage.

As expected middle ear fluid and hemorrhage were predominant in negative pressure animals and the amount and occurrence correlated with the degree of pressure applied. The observation that fluid influences the ossicular chain (12, 16 33) was substantiated by the present investigation The effects of fluid removal are greater for the lower frequencies where middle ear mechanisms play a major role in sound transmission.

In general, the higher negative pressure animals demonstrated a greater amount of middle ear hemorrhage than the lower pressure animals Such animals exhibited the greatest

bution of different frequencies of stimulation to the response of the cochlea. On the basis of a study performed by one of the authors (Mc Pherson, 29) we do suggest that for the recording of cochlear microphonic activity to stimuli above a frequency of approximately 2 000 Hz the round window provides an adequately sensitive recording site. Recordings from this site, however cannot be expected to be sensitive to restricted differential changes in responsiveness occurring along the Organ of Corti (39 40)

In regard to histopathology there are a number of specific observations reported in this paper which should be viewed with the technical approach and animal model we used well in mind. It appears that the present material is often afflicted by cochlear pathology presumably without relation to the induced middle ear pressures. In one animal which was to be included, no electrophysiological measurements could be obtained. This cochlea demonstrated a severe degeneration of all intracochlear structures The most common pathological findings were pigment abnormalities in the stria vascularis and an increased number of melanocytes in the spiral prominence and in the vestibular membrane, particularly at the attachment of the external wall. These changes may indicate aging or other degenerative processes or genetic characteristics

In many cases, the inspection of the middle ear through the otomicroscope at the end of the two-hour experimental period did not disclose any middle ear hemorrhage However later hemorrhages were found in the middle ear and could have at times been caused by widening of the bulla hole that was made in order to inspect the ossicles and the round and oval windows at the end of the experiment. On the other hand, obviously minor hemorrhages could have been missed during the inspection made through the small bulla hole

The occurrence of blood in the contralateral cochlea of two guinea pigs where hemorrhage was also found in the experimental ear is difficult to explain but may be due to technical reasons. Such inner ear hemorrhages have also been encountered occasionally in previous experiments and may besides being induced by technical deficiencies, also reflect an occurrence of spontaneous hemorrhage in the inner ear of the guinea pig.

By comparison with other pathological investigations (30 31 32) perfusion and intravascular injection of the middle ear and cochlea of these animals was far less successful. This appears to be the result of the pathological variable middle ear pressure exposure, rather than to electrophysiological recordings and preparation. We did not see as many problems with vascular perfusion in other longterm electrophysiological preparations. It must be pointed out, however that our previous experiences with animals in which any kind of assessment of the middle or inner ear is made leads to a less favorable outcome of subsequent contrast injection when compared with normal intact preparations. A frequent unexpected finding in this regard was the observation that many control ears were also poorly injected. In most cases, there was a very close correlation between the experimental and the control ear There was a correlation between amount of pressure that the animal was exposed to and the outcome of the perfusion in both ears. These observations suggest that exposure to two hours of middle ear pressure may have a general systemic effect on the vasculature (possibly mediated via the autonomic nervous system). The occurrence of contrast in the vessels is by no means necessary for the interpretation of cochlear vascular pathology With phase contrast microscopy the vessels including the lumen and wall are still easily observable. It is interesting to note that in the present investigation pathological findings were already observed on the longitudinally sectioned surface of the cochlea after decalcification. The section was carefully made, usually in the baso-apical direction with a sharp razor blade. In the early experiments the fixative was injected through the cochlear windows and apex. This and the subsequent sectioning of the cochlea may all have influenced the integrity of the vestibular and basilar membranes. Consequently

middle ear dynamics between man and guinea pig.

The occurrence of inner ear hemorrhage is consistent with previous experiments (24 38). The origin of hemorrhage is an unanswered question Only in a single case could the hemorrhage be related to a particular vessel In no case was a hemorrhage related to any injected contrast outside vessels or to an observed rupture of vessels. It was most commonly demonstrated in the scala tympani close to the round window and in the immediate neighborhood of the cochlear aqueduct It may be that the hemorrhage either originated from cochlear aqueduct or was on its way in the opposite direction "to be drained" via the cochlear aqueduct.

A correlation between increased middle ear pressure and cochlear hemorrhage was clearly shown Further these animals without inner ear hemorrhage showed consistent findings compatible with a low middle ear pressure i e four had a tympanic membrane perforation, and two animals belonged to the lowest negative pressure group (−50 −100 mm H_2O) Therefore the absence of cochlear hemorrhage emphasizes the relation of middle ear pressure and inner ear histopathology It appears that high pressure may cause either a tympanic membrane perforation or an inner ear hemorrhage The absence of round window perforations indicates a greater round window membrane resistance to pressure trauma than for the tympanic membrane in the guinea pig.

It is obvious that forces which may induce cochlear hemorrhages also may distend and rupture delicate membranes of the inner ear In this connection, it may be emphasized that the vestibular membrane appears to be quite elastic and distends greatly before rupturing. A moderate distention or collapse of the vestibular membrane was a frequent finding in the present investigation With the present technical approach it is impossible to determine whether this was due to applied middle ear pressure or to the technical assessment of the cochlea or both In some instances, however the distention of the vestibular membrane was very marked (Fig. 21) which could hardly be explained by any of the technical procedures involved One additional weak spot in the cochlea appeared to be the basilar membrane i e the zona pectinata The common nicking of this part of the cochlea and splitting up of the layers (Fig. 21) may again be due to the technical assessment or to the pressure changes Even if this nicking can be explained by the histological procedures as evidenced by similar but less marked nicking in the control ear this area of the basilar membrane appears to be a vulnerable site in the cochlea for different kinds of trauma.

In two cases, one with high positive pressure and one with moderate negative pressure, small "bubbles were found in the inner ear It must be emphasized that discrete bubbles located at sites in the cochlea other than near the round window membrane could not have been observed with the present approach. The occurrence of bubbles" may consequently have been higher than was found We have no suggestions regarding the origin of these bubbles

TECHNICAL CONSIDERATIONS

In evaluating the observations made in this study and interpreting their significance, certain technical considerations must be kept well in mind In regard to the electrophysiological observations, the reservations are basically two (1) the use of anesthesia and (2) the use of round window recording procedures. The use of anesthesia is of course an undesirable albeit appropriate, requirement of such investigations. Physiological evidence indicates that anesthetics effect on the receptor electrophysiological responsiveness may not be great (25)

In regard to the round window recordings it might be suggested that these are not as sensitive to changes occurring at the apex of the cochlea as they are to changes occurring at the base close to the recording electrode Thus, changes in response to high and low frequency stimuli may have been differentially recorded However presently it is not possible to evaluate the contri

ings include the interesting observation of an intact round window membrane, a clear endolymph, and a normal Organ of Corti in all cases. Positive findings were a high frequency of hemorrhage, most commonly demonstrated in the scala tympani of the basal turn close to the round window. The origin of the hemorrhages could not be demonstrated with the present investigation. The hemorrhages often appeared to be related to the cochlear aqueduct. The occurrence of hemorrhage was clearly related to increased negative pressure and the nonexistence of hemorrhage was always related to either tympanic membrane perforations or low applied pressure. Further frequent findings were distention, collapse, and rupture of the inner ear membranes which must be interpreted with great circumspection due to the method used. Likewise, some of the pathological cochlear findings may be due to pathological conditions which are not necessarily related to induced middle ear pressure.

when abnormalities in these membranes were found the injection of fixative was abandoned and the cochleas immersed in the fixative. However we still feel that deviations of these membranes from a normal position must be interpreted with great circumspection Since the Organ of Corti was in all cases found to be normal it may be suggested that in future experiments of the same kind openings of the cochlea for fixative purposes should be limited to the round and oval windows.

Interpretation of distortion and changes in the membranes within the cochlea is difficult with this or any other histological approach that we have been able to think of Possibly the conventional temporal bone embedding procedure is the only one available which may not immediately influence the cochlear membranes Although these reservations are serious control observations did not show such pronounced changes in the position of the membranes of the labyrinth Consequently similar to the deficient vascular contrast injection the changes in membrane position may indeed be the result of this longterm middle ear pressure exposure

CLINICAL ASPECTS

It is obviously tempting to make comparisons between the present experiment and the situation of the human in diving conditions. However simultaneously many concerns arise in doing so with respect to the difference of the experimental approach to the middle ear biological differences etc Further in the human diver another factor influences both the middle and inner ear i e., the ability to equalize pressure This factor was kept stable in the present experiment, i e no equalization of middle ear pressure was achieved spontaneously In this respect the experimental model may be considered to be similar to the diver who cannot perform the Valsalva maneuver The middle ear findings tend to substantiate previous findings of aural barotrauma in the human very closely The inner ear findings, however did not confirm previous findings of window membrane rupture They tend more to correlate with previous findings of sudden inner ear membrane breaks (41 42) It may be suggested from the findings of the pres nt investigation that inner ear hemorrhage is an alternative explanation for sudden hearing loss in connection with diving Further it is felt that similar to the healing of inner ear membrane breaks this hemorrhage may be absorbed or drained with a final recovery of hearing. From the present experiment it would appear that the cochlear aqueduct takes a great part in the clearing of the scala tympani perilymph. This hypothesis is also supported by other previous investigations (43 44 45)

Summary

The electrophysiological findings show a time and pressure related decrease in function of the CM and the N_1 potentials. Sudden changes were correlated with tympanic membrane perforations Some of the decreased function is accounted for by middle ear effusion and hemorrhages, reducing mechanically the transmission of sound energy through the middle ear This was evidenced by an improvement of function when the fluids were removed Remaining decreases in function were interpreted as a result of influences on the inner ear function or of undisclosed middle ear changes. No differences were noted in cochlear function between animals subjected to sustained or intermittent middle ear pressures. Neither were any morphological differences noted between these two groups in the middle or inner ear

The morphological middle ear findings correlated well with previous clinically and experimentally induced changes with increased/decreased middle ear pressure The cochlear find

ings include the interesting observation of an intact round window membrane, a clear endolymph, and a normal Organ of Corti in all cases. Positive findings were a high frequency of hemorrhage, most commonly demonstrated in the scala tympani of the basal turn close to the round window. The origin of the hemorrhages could not be demonstrated with the present investigation. The hemorrhages often appeared to be related to the cochlear aqueduct. The occurrence of hemorrhage was clearly related to increased negative pressure, and the nonexistence of hemorrhage was always related to either tympanic membrane perforations or low applied pressure. Further frequent findings were distention, collapse, and rupture of the inner ear membranes which must be interpreted with great circumspection due to the method used. Likewise, some of the pathological cochlear findings may be due to pathological conditions which are not necessarily related to induced middle ear pressure.

CONTENTS

This work as supported by grants from the Deutsche Forschungsgemeinschaft

I Introduction

Many experiments have shown (see Dallos, 1973) that the functions of the inner ear are intimately connected with the unique ion composition of the endolymph, which is characterized by very high potassium and very low sodium concentrations (Smith et al., 1954). The maintenance of these ion concentrations essentially depends on the structure and functional integrity of the plasma membranes of those cells, which represent the barriers between the different inner ear compartments: (1) endolymphatic space, (2) perilymphatic spaces, (3) intercellular spaces of the stria vascularis. The same is true for the maintenance of the resting potentials of the inner ear which were first described by von Bekesy (1952) and also for the ability of the inner ear hair cells to develop receptor potentials. It is established that the epithelial cells and their zonulae occludentes (Farquhar and Palade, 1963) lining the endolymphatic space constitute the perilymph-endolymph-barrier (see Jahnke, 1973).

The freeze-etch technique has become an important investigative method in studying the fine structure of biological membranes. In the freeze fracture process the fracture occurs through the hydrophobic core of the membrane (Branton, 1966), exposing two intramembranous fracture faces: the fracture face A adjacent to the cytoplasm, and the fracture face B adjacent to the extracellular space. Both fracture faces show globular particles of variable sizes which are believed to be proteins and lipoproteins (Boetscher, 1973; Packer, 1974). They are cytoplasmically synthesized and swim in the phospholipid bilayer (fluid mosaic model of Singer and Nicolson, 1972). The intramembranous particles are preferentially associated with the A fracture face.

Intercellular junctions are also split by freeze fracture revealing their internal macromolecular architecture. Thus zonulae occludentes exhibit the presence of a branching and anastomozing network of ridges on the A fracture face and a complementary network of grooves on the B fracture face (Kreutziger, 1968; Staehelin et al., 1969). There is evidence that the fibrils of the network are the sealing component of the junction (Goodenough and Revel, 1970; Friend and Gilula, 1972). In a recent paper a single fibril model for the zonula occludens was proposed (Wade and Karnovsky, 1974 a).

The purpose of this paper is to describe the distribution, size and configuration of freeze-fractured intercellular junctions of the perilymph-endolymph barrier with special reference to the plasma membrane structures of the inner ear sensory epithelia. It includes the results of an examination of freeze-fractured inner ear synaptic membranes. A preliminary report of freeze-fracturing of cochlear tissues has appeared elsewhere (Jahnke, 1974).

The freeze-etched fine structure of the stria vascularis has previously been reported in detail (Jahnke, 1975).

II Material und Methods

14 pigmented guinea pigs (6 male, 8 female), weighing [illegible]35–360 g, were anesthetized by intraperitoneal injection (30–35 mg/kg body weight) of Nembutal sodium. The right cochlea of 9 animals was exposed, and a hole was made in its apex, and then both the oval and the round window were opened.

Subsequently the cochlea was perfused with 2% paraformaldehyde 2,5% glutaraldehyde in 0 1 M cacodylate buffer (pH 7 4) for 5–10 min. Following decapitation the temporal bones were removed and dissected The inner ears remained in identical aldehyde solutions for 2 hours at 0–4 C, and were carefully washed and stored in 0 1 M cacodylate buffer The tissue was then soaked in 20% glycerol in 0 1 M cacodylate buffer Tissue from 8 animals was glycerinated without the use of chemical fixatives.

Small dissected specimens from the cochlear duct the saccule the utricule and the cristae ampullares were rapidly frozen in liquid freon 22 cooled by liquid nitrogen. The tissue was fractured and etched (1 min) in a Balzers freeze-etch unit BA 360 M (Balzers AG Liechtenstein) at −100° C. The platinum-carbon replicas were picked up on uncoated grids or formvar membranes and examined with either a Siemens Elmiskop 101 A or a Siemens Elmiskop 1 A at 80 kV

III The perilymph-endolymph-barrier of the cochlea and the compartment of the stria vascularis

A OBSERVATIONS

In order to study the structures which surround the cochlear duct small tissue pieces of all coils were oriented before freezing so that the fracture plane would occur as the usual midmodiolar sections. Frequently some parts were fractured as expected, while in other regions the fractures were oblique to various degrees. The following description is based on the evaluation of aldehyde-fixed tissue compared with unfixed. Only small differences were noted. Generally the fracture plane was more uneven in nonfixed tissue particularly in the region of intercellular junctions. This finding agrees with the report by Staehelin (1973) Descriptions of membrane particle densities are based on fixed specimens although considerable differences in the densities of intramembranous particles (Kirk and Tosteson 1973 McIntyre et al., 1974) were not noted in unfixed inner ear cell membranes. Freeze

When unfixed specimens are shown, this will be specified.

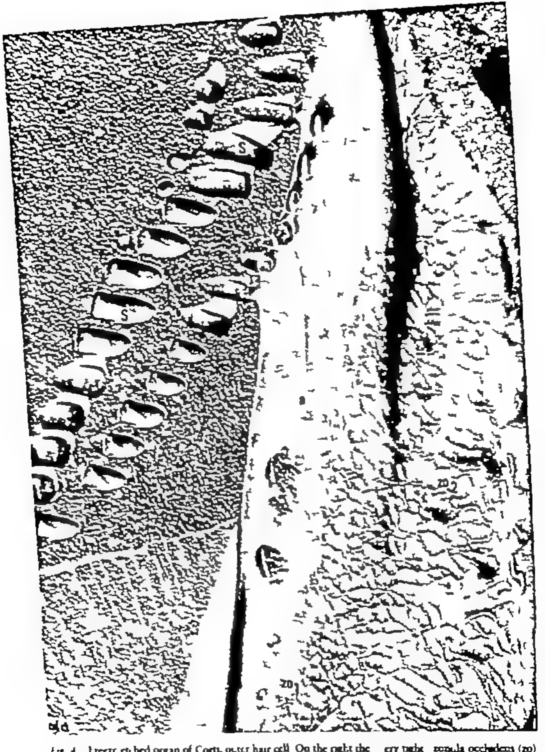

Fig. 4 Freeze etched organ of Corti, outer hair cell. On the right the very tight zonula occludens (zo) can be seen on the B fracture face. The total junctional depth is about 2.0 µm, and there are about 30 strands between the apical and the lateral membrane faces. Two regions of the zonula occludens can be distinguished: (1) an apical region with six to eight horizontally running strands and (2) a large distal zone, which consists of an irregular network of strands. The stereocilia (S) are obliquely fractured, with rather high particle density on their A fracture face and few particles only on their B fracture face. The same is true for the apical membrane face ( ) of the hair cells. dm = upper part of the system of discontinuous membranes. × 30,000

fracture of most *zonulae occludentes* which seal the cochlear duct reveals a band of five to eight interconnecting ridges on the A fracture face and complementary interconnecting grooves on the B fracture face (fig. 1 2, 3 15) This is consistent with the "intermediate to tight" type of zonula occludens (Claude and Goodenough 1973) An important exception is the "very tight" zonula occludens of the reticular lamina in the organ of Corti (see below) Where three cells join the zonula occludens extends basally along the facing lateral cell membranes. There one can observe up to twelve or more strands, of which the lower ones are very short (fig. 15) Some isolated strands are visible basally to the zonulae occludentes. The thickness of the ridges is about 90 Å. Particularly in the region distal to the zonula occludens, single particles can be found (fig. 15) Often in nonfixed specimens and sometimes in fixed specimens the ridges exhibit a particulate substructure and it may be that the particle-free intervals correspond to the particles which are seen in the B-face grooves (fig 4b)

The *zonulae occludentes of the inner and outer hair cells* and the supporting cells which are directly connected with them, are very tight (fig. 4a 4b 5) Two zones can be differentiated There is an apical band which has rather parallel strands, six to eight in number and which is similar to the intermediate to tight zonulae occludentes described above The large distal zone consists of irregular strands which form polygonal fields of very different sizes. In total one can count up to 30 strands or more which form junctions of about 2 μ width On the B fracture face grooves many particles of different size are observed whereas in the polygonal fields there are only a few particles (4b)

Two distinct membrane appearances of the *stereocilia* are produced by the fracture process, a convex A fracture face and a concave B fracture face While one can see a moderate number of diffuse particles on the A fracture face of both the stereocilia membranes and the apical cell membranes, relatively few particles are found on the B fracture face An interesting finding are the A and the B fracture face particles around the base of the stereocilia (fig. 5) In cross fractured stereocilia a fibrillar substructure can be indentified, with a diameter of about 100 Å (fig. 5)

Freeze-etch replicas of the outer and inner hair cells give additional information concerning the *discontinuous membranes* These membrane systems are parallel to the lateral cell membranes and show only some particles when freeze fractured which are mostly clustered around the pores. Their pores are similar to the nuclear pores and are often arranged in circles. The diameter of the pores ranges from 800 to about 1000 Å (fig. 9) The discontinuous membranes have direct contact with the cuticular plate (fig. 4a)

Synaptic membranes also are split by the freeze-fracture procedure (Akert et al., 1972 Pfenninger et al., 1972) Thus in the synaptic regions of the inner and outer hair cells up to eight fracture faces can be observed these are the A and the B faces of the presynaptic as well as of the postsynaptic membrane at both the afferent and the efferent nerve terminals The exact definition of the synaptic membrane faces can be extremely difficult particularly when neither the nerve axoplasm nor the hair cell cytoplasm is cross-fractured and numerous replicas have to be evaluated.

Our preliminary observations of the *hair cell synaptic regions* are as follows cross fractured hair cells have aspects analogous to ultrathin sections (fig. 6 7 8) At the site of afferent transmission some 500–800 Å vesicles can be observed in the cytoplasm. The structure of the subsurface cistern is similarly a single discontinuous membrane (fig. 7) While one can differentiate the vesicle-rich efferents from the afferents in cross fractured nerve terminals, it has not yet been possible to do so when the fracture plane runs in the axolemma. In the latter case the terminals exhibit relatively many A fracture face particles. To date the following structures can be defined on the synaptic membranes of the inner and outer hair cells On the A fracture faces homogenous particles are located in rows (fig. 8) and other homogenous particles are arranged in a thumb-print like scanning pattern, with a diameter of 80–90 Å (fig. 7 8) and a center-to-center distance of about 90 Å The distance between the latter rows is about 170 Å (fig. 7) An

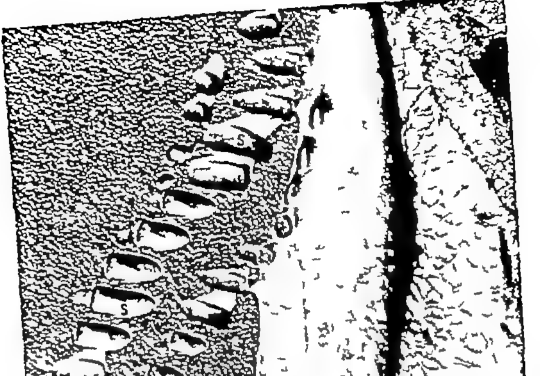

Fig. 4 Freeze-etched organ of Corti, outer hair cell. On the right the very tight zonula occludens (zo) can be seen on the B fracture face. The total junctional depth is about 2.0 µm, and there are about 30 strands between the apical and the lateral membrane faces. Two regions of the zonula occludens can be distinguished: (1) an apical region with six to eight horizontally running strands and (2) a large distal zone, which consists of an irregular network of strands. The stereocilia (S) are obliquely fractured, with rather high particle density on their A fracture face and a few particles only on their B fracture face. The same is true for the apical membrane face (a) of the hair cells. dm = upper part of the system of discontinuous membranes. × 30 000.

fracture of most *zonulae occludentes* which seal the cochlear duct reveals a band of five to eight interconnecting ridges on the A fracture face and complementary interconnecting grooves on the B fracture face (fig. 1 2, 3 15) This is consistent with the "intermediate to tight"-type of zonula occludens (Claude and Goodenough 1973) An important exception is the "very tight" zonula occludens of the reticular lamina in the organ of Corti (see below) Where three cells join the zonula occludens extends basally along the facing lateral cell membranes. There one can observe up to twelve or more strands, of which the lower ones are very short (fig. 15) Some isolated strands are visible basally to the zonulae occludentes. The *thickness of the ridges is about 90 Å. Particularly* in the region distal to the zonula occludens single particles can be found (*fig. 15*) *Often in nonfixed* specimens and sometimes in fixed specimens the ridges exhibit a particulate substructure, and it may be that the particle free intervals correspond to the particles which are seen in the B-face grooves (fig. 4b)

The *zonulae occludentes of the inner and outer hair cells* and the supporting cells which are directly connected with them, are very tight (fig. 4a 4b 5) Two zones can be differentiated There *is an apical band which has rather parallel strands,* six to eight in number and which is similar to the intermediate to tight zonulae occludentes described above The large distal zone consists of irregular strands which form polygonal fields of very different sizes. *In total one can count up to 30 strands* or more which form junctions of about 2 μ width. On the B fracture face grooves many particles of different size are observed whereas in the polygonal fields there are only a few particles (4b)

Two distinct membrane appearences of the *stereocilia* are produced by the fracture process, a convex A fracture face and a concave B fracture face. While one can *see a moderate number of diffuse* particles on the A fracture face of both the stereocilia membranes and the apical cell membranes, relatively few particles are found on the B fracture face. An interesting finding are the A and the B *fracture face particles* around the base of the stereocilia (fig. 5) In cross fractured stereocilia a fibrillar substructure *can* be indentified with a diameter of about 100 Å (fig. 5)

Freeze-etch replicas of the *outer and inner hair* cells give additional information concerning the *discontinuous membranes* These membrane systems are parallel to the lateral cell membranes and show only some particles when freeze-fractured which are mostly clustered around the pores. Their pores are similar to the nuclear pores and are often arranged in circles *The diameter of the pores* ranges from 800 to about 1000 Å (fig. 9) The discontinuous membranes have direct contact with the cuticular plate (fig. 4a)

Synaptic membranes also are split by the freeze-fracture procedure (Akert et al., 1972 Pfenninger et al., 1972) Thus in the synaptic regions of the inner and outer hair cells up to eight fracture faces *can be observed; these are the A and the B faces* of the presynaptic as well as of the postsynaptic membrane at both the afferent and the efferent nerve terminals. The exact definition of the synaptic membrane faces can be extremely difficult particularly when neither the nerve axoplasm nor the hair cell cytoplasm is cross fractured and numerous replicas have to be evaluated.

Our preliminary observations of the *hair cell synaptic regions* are as follows cross fractured hair cells have aspects analogous to ultrathin sections (fig. 6 7 8) At the site of afferent transmission some *500–800 Å* vesicles *can be observed in* the cytoplasm The structure of the subsurface *cistern is similarly a single* discontinuous membrane (fig. 7) While one can differentiate the vesicle rich efferents from the afferents in cross-fractured nerve terminals, it has not yet been possible to do so when the fracture plane runs in the axolemma. In the latter case the terminals exhibit relatively many A fracture face particles. To date the following structures can be defined on the synaptic membranes of the inner and outer hair cells On the A fracture faces *homogenous particles are located in* rows (fig. 8) and other homogenous particles are *arranged in a thumb-print-like scanning pattern* with a diameter of 80–90 Å (*fig.* 7 8) and a center to-center distance of about 90 Å. The distance between the latter rows is about 170 Å (*fig.* 7) An

The typical features of a zonula occludens (zo) of the cochlear nsory epithel um are visible in the upper part of the picture Some cross-f actured fibril (f) nside the stereocilia can be seen on the B fracture face of the pical ha cell membrane The diameters of the stereocilia are ery ari- le Only a few particles are observed, which are often situated nea the base of the stereocilia CD = cochlea ct cu = cuticula plate mv = microvill of a neighbouring ph:

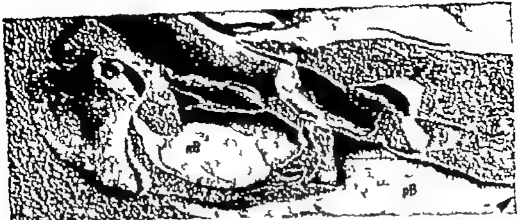

Fig. 11 Freeze-etched tympanic covering layer. Both A and B fracture faces of nexuses or gap junctions (nA, nB) on the mesothelial cells can be observed, although their occurrence is rather rare. The general particle density of the A fracture faces (pA) is much higher than that of the B fracture faces (pB). × 50 000.

other peculiar feature of the hair cell A fracture face is the presence of small depressions. They are complementary to small protuberances on the B fracture faces of the hair cell membrane resembling the protuberances on presynaptic membranes in the central nervous system (Pfenninger et al., 1972).

The nexus (Dewey and Barr 1964) or *gap junction* is probably the type of cell junction responsible for direct electrical and metabolic coupling providing cell-to-cell transfer of ions and cellular metabolites (see Bennett, 1973). In freeze-fracturing the split membranes at the nexus exhibit either arrays of particles about 80 Å in diameter on the A fracture face or complementary arrays of small pits or depressions on the B fracture face. Usually the arrays are hexagonal with 90 to 100 Å center-to-center-spacing (Kreutziger 1968 Chalcroft and Bullivant, 1970). In the spiral ligament many gap junctions are seen on the fibrocytes (fig. 12, 13). They have various sizes and appear to interconnect all cells of the spiral ligament. Such intercellular junctions are also detected between these fibrocytes and the basal cells of the stria vascularis, as was previously reported (Jahnke, 1974 1975). The A fracture faces of the fibrocytes are very particle-rich (fig. 12, 13). By thorough examination one can recognize particles of various sizes (fig. 12, 13). Where the cytoplasm is cross-fractured, fibrils or bundles of fibrils can be distinguished in fairly regular orientation (fig. 13). Scala vestibuli (fig. 11) and scala tympani are lined by some layers of flat mesothelial cells, which are not a true diffusion barrier.

Only a few gap junctions can be observed on the cells of the tympanic covering layer (fig. 11) while there are particle aggregations which are usually interpreted as cross-fractured desmosomal cell contacts (fig. 10).

The nonsensory cells lining the cochlear duct are joined by a few gap junctions, e.g. the epithelial cells of the outer sulcus (fig. 14). The most important finding is that all supporting cells of the organ of Corti are coupled by gap junctions (fig. 15 16 18 19). The size of the nexuses in the organ of Corti is very variable. Generally larger gap junctions are found in the distal supporting cell regions. On the other hand our illustrations show examples of medium to large gap junctions in the upper part of the cells (fig. 15 16) and rather small *gap junctions* basally (fig. 18). Sometimes one may get the impression, that the nexus subunit on *A fracture face* has a *central* depression corresponding to the proposed hydrophilic intercytoplasmic channel (fig. 19) but it cannot be ruled out to be a preparation artifact.

Rectangular arrays of small membrane associated particles 60 to 70 Å diameter is a characteristic and common finding in apical regions of the supporting cells in the organ of Corti as demonstrated in figure 15.

Freeze-fracturing of the inner and outer pillar cytoplasm reveals the fine structure and three-

Fig. 23 The perilymph-endolymph-barrier of the cochlea and the stria vascularis. This diagram summarizes the results of observations on tight junctions, which seal the cochlear duct and the intercellular spaces of the stria vascularis. SV = scala vestibuli, ST = scala tympani, CD = cochlear duct, OC = organ of Corti, S = stria vascularis, SL = spiral ligament. All nonsensory epithelia, which line the cochlear duct, have zonulae occludentes of the intermediate to tight type (dotted line). In contrast, the zonulae occludentes of the cochlear sensory epithelium as well as the tight junctions of basal cells of the stria vascularis are very tight (thick black line). The circles represent blood vessels, which all have tight junctions, such that their nonfenestrated endothelia also form barriers.

Angelborg, 1974) and horseradish peroxidase (Duvall and Sutherland, 1972; Masuda, 1972; Jahnke, 1972 and 1973). Thus it is not surprising that the zonulae occludentes of the nonsensory epithelium of the organ of Corti, such as the Hensen cells are very similar to those of other epithelial cells lining the cochlear duct. We also believe that they maintain the same resting potential difference as the other epithelial cells of the perilymph-endolymph-barrier (see below). The "very tight" zonulae occludentes of the cochlear sensory epithelia are also components of the perilymph-endolymph-barrier. In addition, the numerous strands can be explained by the function of the hair cells as mechanoreceptors. *It is essential that these sensory cells are anchored very firmly in order that disturbance by movements of small molecules can be prevented and that they have resistance to powerful forces which follow intensive noises.*

The fine structure of tight junctions may be changed in some inner ear diseases. Recently Wade and Karnovsky (1974b) demonstrated osmotic

dimensional arrangement of their tubuli (fig. 17 18) Their total diameter is about 260 Å and that of the lumen about 100 Å

In freeze-fracturing one gains additional information concerning the *particle densities* of the apical epithelial cell membranes which line the *cochlear duct* (fig. 1–3 14 16) and particularly the membranes of the microvilli Generally their convex A fracture faces have a medium to high particle density especially in the marginal cells of the stria vascularis the spiral prominence epithelium and some outer sulcus epithelia and the Hensen cells.

The *spiral vessel the vessels of the spiral ligament the spiral limbus and the stria vascularis* are nonfenestrated. Their endothelial cells are connected by tight junctions. In freeze-fracture replicas these tight junctions consist of very differing numbers of strands in the same region. The arrangement of the strands and their substructures have a closer resemblance to the strands of the basal cells of the stria vascularis than they have to epithelial cells. Of special interest is the presence of a particulate substructure in the tight junctions of the vessels. Other features of freeze fractured vessels are very high particle densities particularly in the vessels of the stria vascularis and a varying frequency of micropinocytotic vesicles The latter are mostly seen as invaginations on the A fracture face (fig. 20) and as protrusions on the B fracture face. In some capillaries of the stria vascularis and of the spiral prominence nexuses were present connecting endothelial cells

In order to give a more complete picture of the tissues which surround the cochlear duct the freeze-fractured fine structure of the *stria vascularis* will be briefly summarized Whereas the marginal cells and their intermediate to tight zonulae occludentes represent the barrier between the endolymphatic space and the stria vascularis intercellular spaces, the latter are sealed to the spiral ligament by the "very tight tight junctions of the basal cells (fig. 21 22) Thus it is confirmed that the intercellular spaces of the stria vascularis are a compartment. The tight junctions of the basal cells exhibit a network of strands, and a particulate substructure – on the B fracture face – is noted more often than in the epithelial tight junctions. Thin tenuous grooves associated with slight membrane elevations (fig. 21) can be observed on the A fracture faces. Within these areas gap junctions are often seen Of special importance is the finding that all stria vascularis cells are coupled by gap junctions. Another notable feature is that the marginal cell membranes particularly the membranes of their extensions are extremely particle rich (fig 22) a sign of very high metabolic activity

B DISCUSSION

The results of our observations on the perilymph endolymph-barrier of the cochlea as well as the compartment of the *intercellular spaces of the stria vascularis* are summarized in figure 23 In general the zonulae occludentes of the nonsensory epithelia which seal the cochlear duct consist of approximately four to eight horizontal strands. According to the report by Claude and Goodenough (1973) thus is the "intermediate to tight"-type of zonula occludens. These authors compared electrophysiological and fine structural observations with respect to the transepithelial permeability They found that junctions of "tight epithelia show five or more strands, whereas in leaky epithelia" only a few strands are present Their findings agree with the results of Friend and Gilula (1972) and other authors. It is well known that in regions where three epithelial cells are in contact the zonula occludens extends basally and shows more strands (see Staehelin, 1973) Our findings indicate that epithelia with zonulae occludentes which consist of four to eight strands, are able to maintain the resting potential difference of about 90 mV between the cochlear duct and the perilymphatic spaces. The same is true for the marked electrolyte concentration gradients between the potassium-rich endolymph and the sodium-rich perilymph It must be pointed out that *active membrane processes* also play an essential role.

Tasaki et al. (1954) postulated that the electrolyte concentrations of the intercellular fluid of the organ of Corti ("cortilymph") are similar to those of the perilymph. This has been supported by several tracer studies with thorotrast (von Ilberg, 1968b;

particle rows of the nerve terminal membranes of motor endplates which may be associated with synaptic vesicle fusion and transmitter release (Dreyer et al., 1973 Rash and Ellisman, 1974)

Electrotonic coupling is characterized by a low ohmic resistance to the intercellular passage of ions. Nexuses are the cell junctions which are thought to provide cell-to-cell transfer of ions by means of their intercytoplasmic channels (see McNutt and Weinstein, 1973 Bennett, 1973) Such transfer is presumably also possible for cellular metabolites (Gilula et al., 1972). The closely packed globular particles on the A fracture face are interpreted as the morphological correlates of the hydrophilic channels.

In the present study it was demonstrated that coupling of cells by nexuses is a very common feature of cochlear tissue. In this respect the most important finding is perhaps that nexuses connect all supporting cells of the organ of Corti. There is negative resting potential of about 70 mV and it is still uncertain whether it was measured intracellularly or extracellularly (see Dallos, 1973) One of the arguments against the first suggestion is that it is technically difficult to obtain pure intracellular readings. However our results which indicate that there is electrotonic coupling of all supporting cells in the organ of Corti by nexuses, are at variance and suggest that it is possible to measure the resting potential intracellularly. It has been previously reported and discussed in detail (Jahnke 1975) that all cells of the stria vascularis are coupled by nexuses. In this connection it is of interest that the spiral ligament fibrocytes are also coupled with the basal cells of the stria vascularis by such junctions. One prerequisite for the formation of nexuses between the basal cells and the fibrocytes may be that the stria vascularis cells lack a basement membrane.

The rectangular arrays of particles which occur on plasma membranes of the supporting cells of the inner ear sensory epithelia will be discussed in part IV

The endothelial cells of the inner ear capillaries represent the site of the blood-perilymph-barrier except for some fenestrated capillaries of the cochlear plexus. Tight junctions are located between the plasma membranes of these endothelial cells, and they are impermeable to tracers such as horseradish peroxidase (Jahnke and Gorgas, 1974) Now freeze-fracture replicas of inner ear capillaries have revealed the fine structure of the tight junctions. Since they are composed of single particles they are more similar to the network-like tight junctions of the basal cells of the stria vascularis (Jahnke, 1975) than to the zonulae occludentes of the epithelial cells of the cochlear duct. That is a one could expect because both the capillary endothelial cells and the basal cells are of mesenchymal origin. In the regenerating rat liver Yee and Revel (1975) observed similar particles in regions of contact between endothelial cells lining the hepatic sinusoids. The number of strands can be very variable, and one can gain the impression of rather "leaky" and of "tight" type functional regions next to each other

IV The vestibular sensory epithelia

A OBSERVATIONS

The freeze fracture observations on the maculae sacculi et utriculi and on the cristae ampullares will be described together because the results agree in all essential points.

The *zonulae occludentes* of the vestibular nonsensory regions are of the "intermediate to tight" type (fig. 29), whereas all vestibular sensory epithelia are sealed by zonulae occludentes of the "very tight" type (fig. 24, 25a 27 28, 35a) Here one can also distinguish a small apical zone with more *parallel strands* and a *large* distal zone with a net work of strands. It should be pointed out that the strands are less frequent than in the organ of Corti. Especially the distal network is looser and single strands can be seen more often (fig. 25a, 28)

The stereocilia of the vestibular hair cells show

disruptions of single strands of the zonulae occludentes in the toad urinary bladder which are reversible. In the pathogenesis of Menière's disease *alterations of the osmotic pressure of the endolymph* are thought to be an essential step. These *could produce disruptions of single strands of the* zonulae occludentes which seal the endolymphatic space. The zonulae occludentes would become "leaky" and the following ion concentration changes would lead to a decrease of the microphonics. In our opinion this may explain the hearing fluctuations which occur in patients with Menière's disease. Acute acoustic trauma also may cause disruptions of single zonula occludens strands.

Intramembranous particles represent the protein component of membranes (see Bretscher 1973). Their higher frequency on the A fracture faces of the membranes is due to the fact that the membranes are asymmetrical and contain more protein in their cytoplasm adjacent layer. The particles on the B fracture face are thought to be proteins or parts of proteins which extend from one cell membrane surface to the other. Such particles *appear to be involved in transport particularly of* small molecules, e.g. ions, H_2O, glucose (see Fox 1972) *and are called "carrier" proteins. In this* connection the particle pattern on the B fracture faces may be more interesting than on the A fracture faces. But it cannot be ruled out that some of the A fracture face particles are also carrier proteins.

The relatively few particles on the B fracture faces of the hair cell apical membranes and their stereocilia may explain the very high potential difference (> 150 mV) between the cochlear duct and the hair cells of the organ of Corti. It may be important for mechano-electric transduction *that there are some clusters of particles on the B fracture faces near the bases of the stereocilia.* It is suggested that the receptor potentials develop when the membrane resistence of the apical hair cell membrane has changed. Flock (personal communication 1975) has shown in the lateral line organ of the burbot that the hairs of the sensory cells are stiff and that they are not bent but angled. This angulation may induce changes in ion-specific resistance in the apical hair cell membrane. The particles may be morphologically analogous to ion-channels, and their configurations could be altered in this way.

The high particle densities of some apical nonsensory cell membranes lining the cochlear duct such as the marginal cells of the stria vascularis, are a sign *of high metabolic activity.* This is also a prominent feature of the cell membranes of the marginal cell extensions, *as previously reported in detail* (Jahnke, 1975). This also applies to some vessel cell membranes, *particularly in the stria vascularis.* As yet the appearance of other particles seen in special regions such as in regions of the discontinuous membranes, cannot be interpreted. It should be noted however that they occur in fixed and in unfixed tissues.

The observations on the synaptic membrane faces are preliminary because only relatively few synaptic membranes can be viewed at an appropriate angle.

The protuberances on the B fracture faces of the hair cells are presynaptic protuberances (see IV B) and are consistent with findings in the central nervous system (Pfenninger et al. 1972). *These authors* have presented data that the protuberances are *temporary attachment (or fusion) sites between* synaptic vesicles and the presynaptic membrane and may be identical with the sites of transmitter release. A hexagonal arrangement of protuberances could not be demonstrated in this study. At nerve terminals in the spinal cord the number of protuberances is decreased in anesthetized as compared with unanesthetized animals (Streit et al. 1972). We do not suppose that the fine structure of presynaptic membranes at the *synapses of the* inner ear is changed to such an extent in anesthe*tized guinea pigs.* The special thumbprint like particle pattern on the A fracture face of the hair cell synaptic membrane cannot be interpreted since only a few of such membranes have been clearly differentiated. The particles may be morphological equivalents of transmitter receptors or ion channels, – we do not know yet if this is a presynaptic or postsynaptic membrane *differentiation.* The two parallel rows of particles on the A fracture faces of the hair cells resemble the similar

particle rows of the nerve terminal membranes of motor endplates which may be associated with synaptic vesicle fusion and transmitter release (Dreyer et al., 1973 Rash and Ellisman, 1974)

Electrotonic coupling is characterized by a lowered resistance to the intercellular passage of ions. Nexuses are the cell junctions which are thought to provide cell-to-cell transfer of ions by means of their intercytoplasmic channels (see McNutt and Weinstein, 1973 Bennett 1973) Such transfer is presumably also possible for cellular metabolites (Gilula et al., 1972) The closely packed globular particles on the A fracture face are interpreted as the morphological correlates of the hydrophilic channels.

In the present study it was demonstrated that coupling of cells by nexuses is a very common feature of cochlear tissue In this respect the most important finding is perhaps that nexuses connect all supporting cells of the organ of Corti. There is a negative resting potential of about 70 mV and it is still uncertain whether it was measured intracellularly or extracellularly (see Dallos, 1973) One of the arguments against the first suggestion is that it is technically difficult to obtain pure intracellular recordings. However our results which indicate that there is electrotonic coupling of all supporting cells in the organ of Corti by nexuses, are at ... ance and suggest that it is possible to measure the resting potential intracellularly It has been previously reported and discussed in detail (Jahnke 1975) that all cells of the stria vascularis are coupled by nexuses. In this connection it ... of interest that the spiral ligament fibrocytes are also coupled with the basal cells of the stria vascularis by such junctions. One prerequisite for the formation of nexuses between the basal cells and the fibrocytes may be that the stria vascularis cells lack a basement membrane

The rectangular arrays of particles which occur on plasma membranes of the supporting cells of the inner ear sensory epithelia, will be discussed in part IV

The endothelial cell of the inner ear capillaries represent the site of the blood-perilymph-barrier except for some fenestrated capillaries of the cochlear plexus. Tight junctions are located between the plasma membranes of these endothelial cells, and they are impermeable to tracers such as horseradish peroxidase (Jahnke and Gorgas 1974) Now freeze-fracture replicas of inner ear capillaries have revealed the fine structure of the tight junctions. Since they are composed of single particles they are more similar to the network-like tight junctions of the basal cells of the stria vascularis (Jahnke, 1975) than to the zonulae occludentes of the epithelial cells of the cochlear duct That is as one could expect because both the capillary endothelial cell and the basal cells are of mesenchymal origin. The number of strands can be very variable, and one can gain the impression of rather "leaky and of tight" type junctional regions next to each other

IV The vestibular sensory epithelia

A OBSERVATIONS

The freeze fracture observations on the maculae sacculi et utriculi and on the cristae ampullares will be described together because the results agree in all essential points.

The *zonulae occludentes* of the vestibular nonsensory regions are of the "intermediate to tight type (fig. 29) whereas all vestibular sensory epithelia are sealed by zonulae occludentes of the very tight type (fig. 24 25a, 27 28, 35a) Here one can also distinguish a small apical zone with more parallel strands and a large distal zone with net work of strands. *It should be pointed out that the strands are less frequent than in the organ of Corti. Especially the distal network is looser and single strands can be seen more often* (fig. 25a, 28)

The *stereocilia* of the vestibular hair cells show

disruptions of single strands of the zonulae occludentes in the toad urinary bladder which are reversible. In the pathogenesis of Menière's disease alterations of the osmotic pressure of the endolymph are thought to be an essential step. These could produce disruptions of single strands of the zonulae occludentes which seal the endolymphatic space. The zonulae occludentes would become "leaky" and the following ion concentration changes would lead to a decrease of the microphonics. In our opinion this may explain the hearing fluctuations which occur in patients with Menière's disease. Acute acoustic trauma also may cause disruptions of single zonula occludens strands.

Intramembranous particles represent the protein component of membranes (see Bretscher, 1973). Their higher frequency on the A fracture faces of the membranes is due to the fact that the membranes are asymmetrical and contain more protein in their cytoplasm adjacent layer. The particles on the B fracture face are thought to be proteins or parts of proteins which extend from one cell membrane surface to the other. Such particles appear to be involved in transport particularly of small molecules, e.g. ions, H_2O, glucose (see Fox, 1972) and are called "carrier" proteins. In this connection the particle pattern on the B fracture faces may be more interesting than on the A fracture faces. But it cannot be ruled out that some of the A fracture face particles are also "carrier" proteins.

The relatively few particles on the B fracture faces of the hair cell apical membranes and their stereocilia may explain the very high potential difference (> 150 mV) between the cochlear duct and the hair cells of the organ of Corti. It may be important for mechano-electric transduction that there are some clusters of particles on the B fracture faces near the bases of the stereocilia. It is suggested that the receptor potentials develop when the membrane resistence of the apical hair cell membrane has changed. Flock (personal communication, 1975) has shown in the lateral line organ of the burbot that the hairs of the sensory cells are stiff and that they are not bent, but angled. This angulation may induce changes in ion-specific resistance in the apical hair cell membrane. The particles may be morphologically analogous to ion-channels, and their configurations could be altered in this way.

The high particle densities of some apical nonsensory cell membranes lining the cochlear duct such as the marginal cells of the stria vascularis, are a sign of high metabolic activity. This is also a prominent feature of the cell membranes of the marginal cell extensions, as previously reported in detail (Jahnke, 1975). This also applies to some vessel cell membranes, particularly in the stria vascularis. As yet the appearance of other particles seen in special regions such as in regions of the discontinuous membranes, cannot be interpreted. It should be noted, however, that they occur in fixed and in unfixed tissues.

The observations on the synaptic membrane faces are preliminary because only relatively few synaptic membranes can be viewed at an appropriate angle.

The protuberances on the B fracture faces of the hair cells are presynaptic protuberances (see IV. B) and are consistent with findings in the central nervous system (Pfenninger et al., 1972). These authors have presented data that the protuberances are temporary attachment (or fusion) sites between synaptic vesicles and the presynaptic membrane and may be identical with the sites of transmitter release. A hexagonal arrangement of protuberances could not be demonstrated in this study. At nerve terminals in the spinal cord the number of protuberances is decreased in anesthetized as compared with unanesthetized animals (Streit et al., 1972). We do not suppose that the fine structure of presynaptic membranes at the synapses of the inner ear is changed to such an extent in anesthetized guinea pigs. The special thumbprint-like particle pattern on the A fracture face of the hair cell synaptic membrane cannot be interpreted since only a few of such membranes have been clearly differentiated. The particles may be morphological equivalents of transmitter receptors or ion channels, – we do not know yet if this is a pre-synaptic or postsynaptic membrane differentiation. The two parallel rows of particles on the A fracture faces of the hair cells resemble the similar

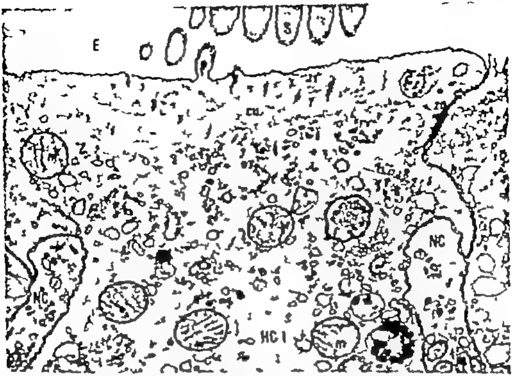

Fig. 26. Micrograph of thin-sectioned sensory epithelium of the crista ampullaris. The stereocilia (S) of the hair cell type I (HCI) are tangentially cut. One can see some of their roots (r) in the cuticular plate (cu). Several mitochondria (m) and many small vesicles occur in the cytoplasm of the hair cell and in the axoplasm of the nerve calyx (NC). On the upper right the zonula occludens (zo) seals the endolymphatic space (E). × 25 000.

Fig. 24. Freeze-etched macula sacculi, apical hair cell region. The bases of cross-fractured stereocilia and some intact stereocilia (S) can be seen. Several particles (p) can be observed on the A fracture face of the apical hair cell membrane particularly near the bases of the stereocilia. mv = microvilli of neighbouring supporting cell, zo = zonula occludens (part). E = endolymphatic space. × 35.000.

Fig. 25 a. Freeze-etched macula utriculi, apical hair cell type I region. The zonula occludens (zoA, zoB) is of the tight type but its distal region is not as large as that of the hair cells of the organ of Corti. There are some isolated strands ( ). The arrow indicates an area where three cells are in contact. S = stereocilia. × 40.000.

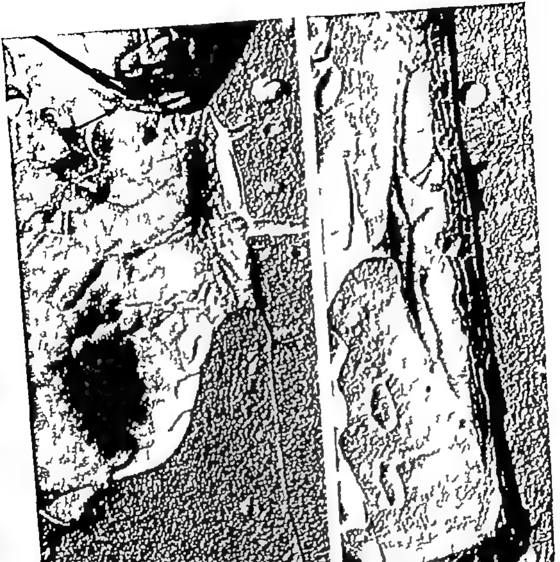

Fig. 27 Freeze-etched crista ampullaris, sensory epithelium. The same region as shown in fig. 26, the hair cell type I is *almost completely detached. The replica exposes the characteristic features of a zonula occludens (zo) of the vestibular sensory epithelium* here seen on the B fracture face. Apically some small horizontal strands can be observed, whereas in the distal region there is an irregular network of strands. Some small protuberances are present on the B fracture face of the hair cell (pt). On the left the nerve calyx (NC) can be seen. E = endolymphatic space. × 35 000.

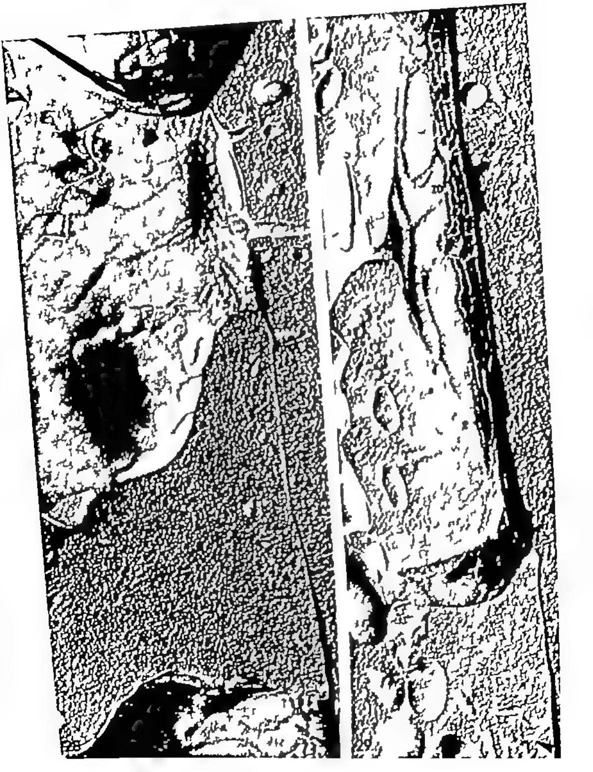
Fig. 28 Freeze-etched macula utriculi, periphery of the sensory epithelium. The zonula occludens ( ) mainly be seen on the B fracture face, with narrow apical strands, whereas some strands extend basally along the facing lateral cell membranes. Arrow indicates, where three cells are in contact. There are several particles on the microvillus *A fracture face (mvA) and only a few on its B fracture face (mvB)* × 48 000

Fig. 29 Freeze-etched macula utriculi, transitional zone. The zonula occludens (zo) *is mostly seen as a series of* ridges on the A fracture face and is composed of at least six strands. × 40.000



F g 30 Freeze-etched macula sa cul sy ptic region of hair cell type I. The ha cell is mostly detached by the freeze fracturing. The view is taken from th position prev ously occupied by the hair cell. The replica reveals the B fracture f ce of the presynaptic ha cell type I membr ne (HCI) and the A fracture face of the postsynaptic nner nerv calyx membrane (NC) The xoplasm of th nerve calyx (x) i cross-fractured. O the presynaptic B fracture f e two regions can be distingu hed (1) there are numerous large particles in one region where s ( ) in another region onl occasional small particles occur In both these reg ons small protuber nces (pt) re present The fra tur exposes n merous small particles and some small depression (de) on the A fracture face of the post synaptic membrane 5 000

a moderate number of diffuse membrane associated particles (fig. 24 25a, 25b) The convex A fracture face contains more particles than the concave B fracture face. On the ciliary membrane only a few diffuse particles can be observed. On the A fracture face of the distal *kinocilium* region, 90 Å particles are arranged around the kinocilium in circles which are bout 800-1000 Å apart (fig. 25b) This membrane differentiation is called the ciliary necklace (Gilula and Satir 1972) I the vestibular sensory epithelia particles are also aggregated around the stereocilia bases (fig. 24)

In the vestibular sensory epithelia of mammals and birds two types of hair cells are found. Hair cells of type I are surrounded by a large afferent nerve calyx, enclosing the major p rt of the flask shaped cell, whereas efferent terminals contact the afferent nerve fibers or the nerve calyx. The hair cells of type II are more oblong, and they are inner vated by mall afferent and efferent nerve terminals on the basal part of each cell (Wersäll, 1956 see Engstrom et al., 1974) On the bottom of both hair cell types synaptic modifications are observed which suggest that there is chemical mode of synaptic transmission. However areas of very close appositions between the nerv calyx and the hair cell type I on its basal part can be seen in thin sections. The possibility of electrical synaptic transmission has been discussed by many authors (see Hamilton, 1968).

As in the organ of Corti, eight different fractur faces (Akert et al. 1972) can also be seen in the *vestibular synaptic regions* Since the hair cell type I is mainly surrounded by an afferent nerve calyx, only four different f acture faces occur in that contact region. The split synaptic hair cell type I membrane represents the presynaptic A and B fracture faces. On its B fracture face areas with high density of large homogenous particles can be dif ferentiated from egions with only a few small particles (fig. 30 31 and b) The large particles ha a diameter of about 130 Å. In both regions many small protuberances (fig. 30, 31a and b) are present which resemble the protuberances of the central nervous system ynapses (Metzinger et al., 1972) Some of these structures usually can also be seen in the upper synaptic zone of the hair cell type I (fig. 27) as well as on the presynaptic B fracture faces of the hair cell type II membrane (fig. 3) Complementary small depressions or pits can be detected on the A fracture faces of the ha r cells. On the A fracture face of the postsynaptic nerve calyx membrane a very high density of homogenous particles is observed. Some small depressions also occur

Other membrane features of the estibular synaptic regions are similar to those in the organ of Corti, e.g. rows of particles on the A fracture face of hair cell type II and particles on the A-fracture faces of nerv terminals. Membrane features which could be interpreted as sites of electrical transmission, have not been found in this material.

All nonsensory epithelial cells of the vestibular apparatus are coupled by *nexuses* e.g. the supporting cells of the cristae ampullares (fig. 33) Below the ery tight zonulae occludentes of the sensory epithelia large gap junctions are situated between tight junction strands which extend basally (fig. 34a, b c) Many small *rectangular arrays* of membrane-associated particles with a diameter of 60 to 70 Å can be seen on the A fracture face of those supporting cells which are adjacent to the nerve calyx (fig. 34a, b, c) They are often composed of only few subunits.

Directly below the zonulae occludentes of *nonsensory estibular epithelia* particle aggregations are present which are considered to be desmosomal contacts.

Freeze-fracture replicas of *vestibular subepithelial vessels* reveal structures similar to those described in the cochlear vessels. The tight junctions consist of ery differing numbers of strands in the same region. Their appearance is illustrated by figures 36a and 36b. In unfixed specimen the particle substructure of the strands is clearly visible.

B DISCUSSION

Many fine structure observations on the freeze fractured membranes of the vestibular apparatus are analogous to those on the membranes of the cochlea which have been discussed above. The zonulae occludentes of all vestibular nonsensory *epithelia* which seal the endolymphatic space con

sist of a similar fine structure as those of the coch lear nonsensory epithelia. They are of the "inter mediate to tight type, whereas zonulae occludentes of the very tight type can be found in the vestibular *sensory epithelia* The latter are com posed of a lower number of strands than those in the organ of Corti. In both sensory areas similar ion concentration gradients have been measured but the difference in the resting potential between the endolymphatic space and the surrounding perilymphatic spaces is much higher in the coch lea than it is in the vestibular labyrinth. Johnstone and Sellick (1973) recorded + 70 to 90 mV in the cochlea, − 8 to + 2 mV in the saccule and − 3 to + 5 mV in the utricle. In addition these authors concluded from their experiments that the utricular endolymph and potential is independent from the cochlea but the saccule derives its potential and endolymph from the scala media via the ductus reuniens The very tight zonulae occludentes are thought to be an essential stability factor for the function of the hair cells as mechanoreceptors.

The remarkable particle aggregations around the bases of the stereocilia could also be observed in the apical cell membranes of the vestibular hair cells It is possible that these particles are morphological equivalents of ionic permeability sites and that they mediate the first step of the mechanoelectric transduction mechanism

Every vestibular hair cell shows one kinocilium on its apical membrane. The fracture faces of the kinocilium membrane contain only a few particles compared with those of the stereocilia However there are particle rows which surround the lower region of the kinocilium membrane just above its junction with the apical cell membrane. This longitudinal arrangement of particles has been de scribed earlier on the A fracture faces of kinocilia in many nonsensory epithelia and has been termed the ciliary necklace which may be involved in energy transduction (Gilula and Satir 1972) The kinocilia of the vestibular sensory epithelia contain a higher number of strands than most of the kinocilia, which were described by these authors, and

Fig 35c. The rectangular arrays (ra) are composed of closely packed particles which have a diameter of 60–70 Å. n = nexus, s = strands. × 100 000

the distance of the single strands is also higher in our material.

All nonsensory epithelial cells of the vestibular labyrinth seem to be electrotonically coupled by nexuses, as it has been shown for the epithelial cells lining the cochlear duct.

Another membrane speciality which also has been found in the organ of Corti, is the rectangular array and this is a very common finding in the vestibular sensory epithelia. Staehelin (1973) described rectangular arrays of A fracture face particles with a center-to-center spacing of approximately 70 Å and complementary pits on the B fracture faces of rat intestinal epithelial cells. These structures were termed "type III" gap junctions. Later on similar rectangular arrays of small particles were observed on the fracture faces of the sarcolemmas of adult rat diaphragm myofibers (Rash et al., 1974). Since these myofibers are separated by basement membranes and are not electrotonically coupled it was concluded that the rectangular arrays of small particles cannot be the morphological or functional equivalents of gap junctions. Similar arrays were observed on freeze-fractured astrocytes (Landis and Reese, 1974), and light cells of the kidney collecting tubule (Humbert et al., 1975). At present, no function is known for the rectangular arrays of small particles. In the astrocytes they have been attributed a possible role in the permeability of the cell membrane (Landis and Reese, 1974). This might be true for the rectangular arrays of supporting cells in both the cochlear and vestibular sensory epithelia. Up to now it cannot be decided, if all supporting cells of the inner ear sensory epithelia are provided with such particle arrays which could be demonstrated in the supranuclear regions of the cells.

Many findings in the vestibular *synaptic regions* were similar to those in the cochlea which have been described and discussed in part III. A special advantage in the study of the vestibular labyrinth is that the hair cell type I-nerve calyx synapse is a synaptic contact of known identity which is thought to be afferent. The B fracture faces of the presynaptic hair cell type I membrane contain aggregations of large particles which we interprete as proteins involved in ion transport. Arrays of small protuberances on the presynaptic B fracture faces and complementary depressions on the A fracture faces have been described in the central nervous system (Akert et al., 1972; Pfenninger et al., 1972; Landis et al., 1974) and also in neuromuscular junctions (Dreyer et al., 1973; Rash and Ellisman, 1974). This prominent specialization of the presynaptic membrane presumably represents the fusion sites between synaptic vesicles and the hair cell membrane where the vesicles release their content of transmitter. Fracture faces of the postsynaptic nerve calyx membrane reveal a high number of particles. Such particles are interpreted as the sites of transmitter receptors, or they may be ion channels or enzymes which catalyze neurotransmitter degradation (Landis et al., 1974). However, it would be premature to discuss the functional significance of these findings in detail, because the chemical nature of the afferent inner ear transmitters is still unknown. At present, there is no evidence that electrical synapses also join the hair cell type I to the nerve calyx.

Application of the freeze-fracture technique to the study of vestibular subepithelial blood vessels confirms our findings in the cochlear vessels. The described structures represent the blood perilymph-barrier. They are of special pathophysiolo-

gical interest if it is supposed that some acute vestibular disturbances in man are due to analogous alterations to those which occur in cochlear vessels in cases of acute hearing loss. On the other hand, resistance changes of the tight junctions of the perilymph-endolymph barrier are thought to develope the equilibrium function disorders in patients with Meniere's disease (see III B)

ABSTRACT

The distribution size and configuration of tight and gap junctions in the guinea pig inner ear were examined in aldehyde-fixed and non fixed freeze etched tissue preparations.

Generally freeze fracture of the zonulae occludentes which seal the endolymphatic space reveals a band of five to eight interconnecting strands. The zonulae occludentes of the cochlear and vestibular sensory epithelia consist of numerous strands and represent the "very tight" type of junction Possible pathological alterations of the tight junctions in some inner ear diseases are discussed.

The supporting cells of all inner ear sensory epithelia as well as all other epithelia lining the endolymphatic space are coupled by many gap junctions of different sizes. Gap junctions are a common finding on the plasma membranes of the fibrocytes of the spiral ligament and – as previously reported – of all cells of the stria vascularis. Rather seldom they can be observed connecting the cells of the tympanic covering layer

The different particle densities of inner ear cell membranes are described in detail At the base of the stereocilia both in the hair cells of the organ of Corti and in the vestibular hair cell particle aggregations can be found which may be the morphological equivalents of ionic permeability sites and may mediate the first step of the mechano-electric transduction mechanism The kinocilia of the vestibular hair cells exhibit a ciliary necklace (Gilula and Satir 1972)

On the A fracture faces of the supporting cells in all inner ear sensory epithelia rectangular arrays of small particles occur

Preliminary results are reported concerning the hair cell synapses of the cochlea and of the vestibular labyrinth The A fracture faces of the inner ear hair cells show 80-90 Å particles arranged in a thumbprint-like pattern. On the A fracture faces of cochlear and vestibular hair cells rows of particles can be seen. Some synaptic cell membrane features of the inner ear hair cell membranes are similar to those observed in the central nervous system at the sites of chemical transmission e g. aggregations of membrane particles and small protuberances occuring on the B fracture faces of presynaptic membranes (Pfenninger et al., 1972) which are interpreted as temporary fusion sites between synaptic vesicles and the presynapatic membrane. The postsynaptic membranes of the nerve calyx which surround the vestibular hair cell type I show a high particle density on their A fracture faces. These particles are interpreted as transmitter receptors.

The fine structure of freeze-etched inner ear blood vessels is described e.g. their tight junctions, particle densities and micropinocytotic vesicles.

The physiological relevance of the findings is discussed with special respect to the barriers which seal the different compartments of the inner ear (perilymphatic spaces, endolymphatic space stria vascularis) as well as to the blood-perilymph-barrier

ZUSAMMENFASSUNG

Mit der Gefrierätztechnik wurden die Permeabilitatsbarrieren untersucht welche die einzelnen Kompartimente des Meerschweinchen-Innenohres bilden. Vorkommen Ausdehnung und Feinstrukturen der interzellulären Verbindungen wie Zonulae occludentes und Nexus wurden beschrieben und ihre funktionelle Bedeutung ausführlich diskutiert. Es wurden weitere neue Befunde an den Zellmembranen des Innenohres und einigen Zellorganellen mitgeteilt die mit dieser Technik zu erhalten waren. Das gilt in besondere fur die Sinneszellen der Cochlea und des Vestibularapparates und ihre Synapsen

Grundsatzlich bestehen die Zonulae occludentes der Epithelzellen die den Endolymphraum abschließen und die Perilymph Endolymph-Barriere bilden, aus einem Band von fünf bis acht annähernd parallel verlaufender Leisten ("Zellmembran-Fusions

lelen"). Sie sind somit hinsichtlich des transepithelialen Widerstandes vom "intermediate to tight" Typ. Die Zonulae occludentes der sensorischen Epithelien des Innenohres weisen zahlreiche Leisten auf, im Cortischen Organ 30 und mehr, und sind folglich vom "very tight" Typ. Gleiches trifft, wie früher berichtet, auf die "tight junctions" der Basalzellen der Stria vascularis zu, die deren Interzellularräume zu den Perilymphräumen des Ligamentum spirale laterale hin abschließen.

Die Stützzellen der sensorischen und viele Zellen der nichtsensorischen Epithelien des Innenohres sind durch Nexus vermutlich elektrotonisch gekoppelt. Zahlreiche Nexus sind auch an den Fibrozyten des Ligamentum spirale laterale und der subepithelialen Gewebe des Vestibularapparates zu beobachten, selten an den Mesothelzellen, welche die Scalen der Cochlea auskleiden. Diese Zellen sind durch zahlreiche Desmosomen verbunden.

Als funktionell bisher nicht zu deutender Befund werden rechteckige Anordnungen kleiner intramembranöser Partikel an den Stützzellen der sensorischen Epithelien beschrieben. Besonderes Interesse gilt auch dem Partikelbesatz der Sinneszellen des Innenohres, dessen Anordnung vor allem in den apikalen Zellmembranen Rückschlüsse auf die Membranfunktionen zuläßt. So sind Partikelansammlungen um die Basis der Stereozilien zu erkennen, die als morphologisches Äquivalent der Ionenkanäle gedeutet werden können, welche in den mechano-elektrischen Transduktionsmechanismus der Haarzellen eingeschaltet sind. Im basalen Bereich der Kinozilien-Membranen der vestibulären Haarzellen verlaufen Partikelreihen circulär, die für die Motilität der Kinozilien charakteristisch zu sein scheinen.

Es werden zahlreiche Membrandifferenzierungen der Synapsen des Cortischen Organs und der vestibulären sensorischen Epithelien beschrieben. Die Haarzellen des Cortischen Organs weisen auf ihren A-Flächen Reihen von Partikeln sowie rasterartig angeordnete Partikelformationen auf, auf ihren B-Flächen sind kleine Protuberanzen zu erkennen, die jenen des Zentralnervensystems entsprechen. Gleiches gilt für die B-Flächen der präsynaptischen Membranen des Haarzelltyp I der vestibulären sensorischen Epithelien. Die Protuberanzen sind sowohl in partikelfreien Membranarealen als auch in Aggregationen größerer (etwa 130 Å Durchmesser) Partikel zu beobachten. Diese Partikel sind als Ionen-Pumpen oder Kanäle zu deuten, die Protuberanzen stellen Fusionsorte synaptischer Vesikel mit der – präsynaptischen – Haarzellmembran dar. Die A-Flächen der postsynaptischen Membranen der kelchartigen Synapsen des Haarzelltyp I haben eine sehr hohe Dichte relativ homogener Partikel, bei denen es sich um Transmitter-Rezeptoren handeln könnte. Weitere Gefrierätzbefunde an den Haarzellsynapsen werden mit denen der Ultradünnschnitt-Technik verglichen. Das gilt ebenfalls für die Feinstruktur der diskontinuierlichen Membransysteme der Haarzellen und der Tubuli der Pfeilerzellen des Cortischen Organs.

Die Gefrierätzabdrücke von Blutgefäßen des Innenohres und deren Strukturen wie "tight junctions", Partikeldichte und mikropinocytotische Vesikel werden beschrieben und hinsichtlich der Bedeutung der Blut-Perilymph-Barriere diskutiert.

Schließlich wird auf pathophysiologische Aspekte dieser Untersuchungen eingegangen. So wird z.B. angenommen, daß das fluktuierende Hörvermögen und die Schwindelattacken bei Morbus Menière durch Widerstandsänderungen der Perilymph-Endolymph-Schranke bzw. ihrer Zonulae occludentes entstehen können.

ACKNOWLEDGEMENT

The excellent technical assistance of Miss Karin Schessl is gratefully acknowledged. I wish to express my sincere appreciation to Ing. Siegfried Böhler and Mr. Remigius Hämmerle, Balzers A.G./F. Liechtenstein for their valuable assistance given me in freeze-etching technique. I thank Mr. Bengt Hedberg for excellent photographic assistance as well as Miss Ann-Marie Lundberg and Mrs. Britta Flock for preparing the illustrations.

Thanks are due to Doz. Åke Flock and Prof. Jan Wersäll for many informative discussions and Dr. David Ballantyne for correcting the English text.

I also thank Prof. Dr. Ottmann and Prof. Dr. Böck, Department of Anatomy, University of Cologne, for use of the electron microscope.

Abstract

Why do animals have intense troubles mainly in the basal turns of their cochleae by the exposure to sound and the ototoxity? I thought that the protein in cells had an important relation to this subject. So I performed this experiment. I made model of hair cells of silicon and poured three kinds of solutions of protein into them. And I checked the ionization of the protein and its denaturation by giving strong energy of oscillation to them like the same idea of photoelectric effect. As the result as for the protein liquid I noticed the increase of volts just after it was exposed to sound and about 3 hours later I observed the figure decreased gradually. From this phenomenon, I presumed that the protein in sensory cells became a factor of the stimulation by receiving strong energy conversely. Low-percent protein liquid had less effect caused by sound

Introduction

Why do animals exposed to strong sound have troubles generally in the basal turns of their cochleae? And why are troubles in the inner ears found among the animals administered ototoxic antibiotics such as streptomycin (SM)? How can hair cells feel sound? Why does tinnitus exist? In the auditory mechanism of the inner ear we still have unknown problems today

The Aim of the Study

I think the protein in the epithelial cells of the inner ear has the closest relation in these subjects. When strong energy is given to protein liquid because it is amphoteric electrolyte ionization occurs (Fig 1) positive ions and negative ions separate and it showed some potential. And when much stronger energy works the protein is supposed to be denatured. I think the same phenomenon like this can take place in the protein of the epithelial cells of animals inner ears too.

And from the process of this denaturation, I thought the auditory functions could be presumed conversely so that I had this experi-

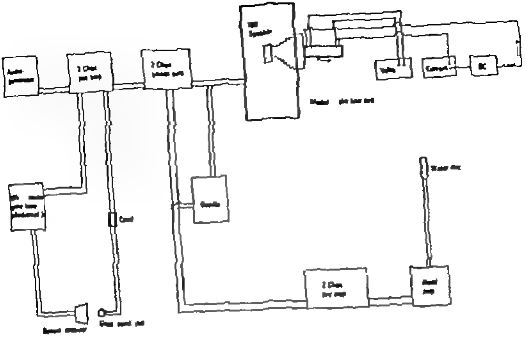

Fig. 4 Sound generator and model of the inner ear

Experiment

I made a model of hair cells in the inner ear and poured a solution of protein into it. According to the law of the energy of oscillation $I = \frac{1}{2}PCW^{2}A$ I tried to record how the change of W affected the energy

- P Density of medium
- C Velocity of oscillation
- W Frequency
- A Amplitude (sound intensity)

and the reaction of the protein.

I performed two sub-experiments on sound before the main experiment.

Sub-experiment I: Test on exposed sounds

Method

I used the experimental apparatus shown in Fig. 4 1 kc/s and 4 kc/s as pure sounds were issued from the receiver of an audio-meter *with a certain loudness (90 db)* and I caught them with an electro-condenser microphone *(Sony II ECM 507702)* and observed them with an oscilloscope To ascertain the quality of sound and the energy by the difference of frequency I observed them through (1) a big hole (2) an ear plug with a fine linear course and moreover (3) an ear plug with a fine spiral course which I made on an experimental basis.

Result

High frequency is hard to go through the fine spiral course That is to say the greater the frequency is the easier it is to be absorbed. In this way I could make sure of decreasing amplitudes as its physical quality (Fig. 5)

Sub-experiment II: Histological examinations in the inner ears of guinea-pigs

Method

A sound source as shown in Fig. 4 (Leader audio generator Sony-stereo amplifier 3130F

	Red	Blue
Frequency	Low	High
Energy	Large	Small
Amplitude	Large	Small
Photoelectric effect	Bad	Good

Fig 2 Properties of wave and oscillation (*a*) Photoelectric effect (*b*) Properties of oscillation in the inner ear The shorter the wave is the more electrons are emitted. Similarity between the photoelectric effect and the inner ear

ment Several kinds of energy of the oscillation are used as the strong energy affecting the protein Just like photoelectric effect the more the frequency the stronger the energy (Figs 2 and 3) And when the protein receives it its molecular structure is destroyed

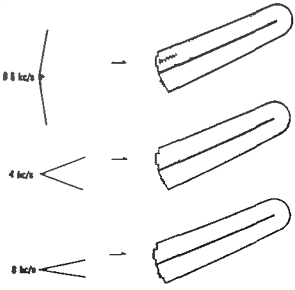

Fig 3 The position and intensity of energy received in the inner ear depends on the difference in frequency

Sony stereo preamplifier 2000F) able to issue up to 100 kc/s is used for pure tone and noise from an audio-meter (Trio Audio-Meter Model AS 91) is used for white noise after it is amplified 12 guinea pigs weighing about 100 g were divided into 4 groups—3 to control 3 were exposed to 1 kc/s 3 to 4 kc/s and 3 to white noise I checked the tissues of their inner ears affected by these frequencies After they were placed about 20 cm in front of a loudspeaker and exposed to the loudness of 95 phone 10 hours a day for a week I took out their cochleae and put them in 10% formalin I also made a slice of the cochlear tissue fixed in the

Fig 6 Changes i the organ of Corti caused by sound ( ) Corti apparatus of the guinea-pig (control) (*b*) after exposure to 1 kc/s, 95 phone for 7 days (*c*) after exposure to 4 kc/s 95 phone for 7 days, (*d*) after exposure to white noise for 7 days 1 kc/s destroyed the basal turn the second nd the third turn 4 kc/s destroyed mainly the basal turn Whit noise destroyed mainly the basal turn and the second turn was slightly damaged

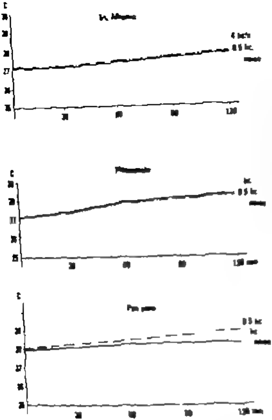

Fig. 10 Temperature (slight increase)

Main experiment

Method

As shown in Fig. 4 mentioned above this experiment is to lead the sound of 105 phone issued from an audio-generator and amplified with a loudspeaker through a 2-channel pre amplifier and a 2-channel power-amplifier to the vibrator of the model of hair cells I used 0.5 kc/s 4 kc/s and white noise as exposed sound

That is to say 4 terminals of platinum and 2 mV and μA-meters were used under the DC volts of 80 mV The model of the hair cells was made of a silicon like a column which had a capacity of about 40 cc and at both ends the substitute of vibrator was made of holl and in the center of the model a pH-meter and a thermometer were inserted (Fig. 7). 5% human albumin, human plasmanate (preserved in a low temperature about 7°C~8°C) were used as solutions of protein (Table I) The used solutions of protein are simple proteins which generate only amino-acid by the hydrolysis

Result

(*a*) Change of current and volts

I recognized the change of volts in 5% albumin and plasmanate . or 3 minutes after sound was exposed in a solution of protein and the values were low in the order of white noise 4 kc/s and 0.5 kc/s and the time of reaction was different each time But I could not recognize a significant change in electric current (Table II Figs 8 and 9)

(*b*) Change of temperature in the protein liquid

Because temperature absorbs the energy of sound a little increase was admitted in 5% albumin plasmanate and pan-amin But there was no change by the difference of frequency (Fig. 10)

(*c*) Change of pH in the protein liquid

In 5% albumin (pH 7 1) there was a little increase of pH after it was exposed to white noise and on the other hand there was no change or a tendency of decreasing to 0.5 kc/s and 4 kc/s. In plasmanate (pH 6.59) and pan-amin (pH 5 97) there existed a tendency of increasing just a little (Fig 11)

Table I *Ingredients of applied protein liquid*

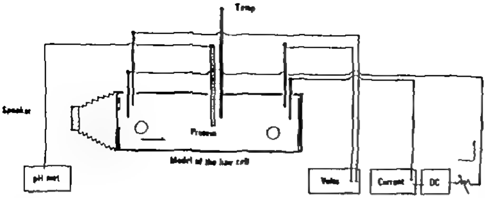

Fig 7 The apparatus for the ionization test of protein The construction was of silicone and had a capacity of 40 cc, a length of 10 cm and a diameter of ..5 cm.

Zelloidin liquid like a pattern after it was dyed in the Haematoxylin Eosin (H E) and I made a microscopic inspection of it

Result

I recognized 1 kc/s caused trouble in their first second and third turns of the three guinea pigs and 4 kc/s caused trouble in the first turn and under the exposure of white noise mainly in the first turn and a little trouble in the second turn (Fig 6) As for the opinions on the troubles in the inner ear caused by pure tone and white noise they are almost the same as the reports in the past (Kawata 1955 Takeda 1960)

The aim of this histological examination is to check the troubled regions of the cochlea and its extent caused by the energy when the frequency was changed and on the other hand the loudness is fixed

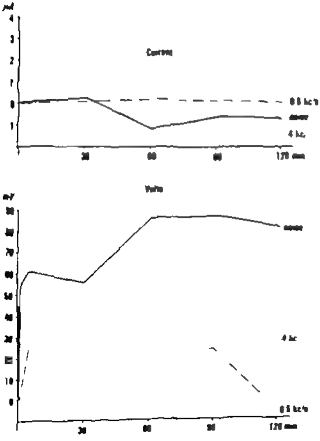

Fig 8 The increase in voltage in the albumin.

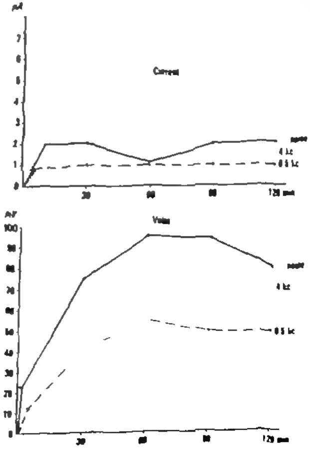

Fig 9 The increase in voltage in the plasmanate

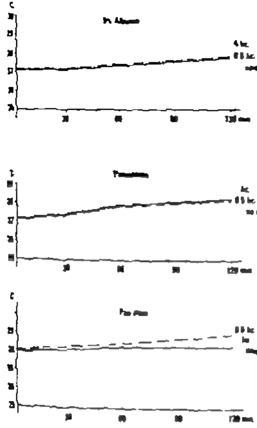

Fig. 10 Temperature (slight increase)

Main experiment

Method

As shown in Fig. 4 mentioned above this experiment is to lead the sound of 105 phone issued from an audio-generator and amplified with a loudspeaker through a 2-channel pre amplifier and a 2-channel power-amplifier to the vibrator of the model of hair cells. I used 0.5 kc/s 4 kc/s and white noise as exposed sound.

That is to say 4 terminals of platinum and 2 mV and μA-meters were used under the DC volts of 80 mV. The model of the hair cells was made of a silicon like a column which had a capacity of about 40 cc and at both ends the substitute of vibrator was made of foil and in the center of the model a pH-meter and a thermometer were inserted (Fig. 7). 5% human albumin, human plasmanate (preserved in a low temperature about 7°C–8°C) were used as solutions of protein (Table I). The used solutions of protein are simple proteins which generate only amino-acid by the hydrolysis.

Result

(*a*) Change of current and volts

I recognized the change of volts in 5% albumin and plasmanate 2 or 3 minutes after sound was exposed in a solution of protein and the values were low in the order of white noise 4 kc/s and 0.5 kc/s and the time of reaction was different each time But I could not recognize a significant change in electric current (Table II Figs 8 and 9)

(*b*) Change of temperature in the protein liquid

Because temperature absorbs the energy of sound a little increase was admitted in 5% albumin, plasmanate and pan-amin. But there was no change by the difference of frequency (Fig. 10)

(*c*) Change of pH in the protein liquid

In 5% albumin (pH 7 1) there was a little increase of pH after it was exposed to white noise and on the other hand there was no change or a tendency of decreasing to 0.5 kc/s and 4 kc/s In plasmanate (pH 6.59) and pan-amin (pH 5 92) there existed a tendency of increasing just a little (Fig. 11)

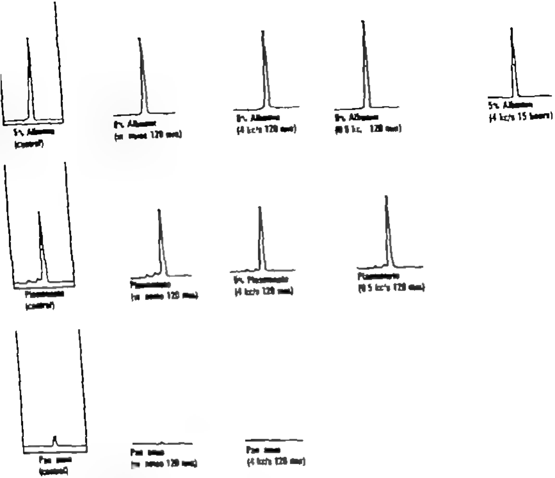

Fig. 13. Change in the electrophoretic test. The albumen curve began to fall from its peak 15 hours after the power to sound (right side)

(*d*) Denaturation test on the proteins

There was almost no change in osmotic pressure, viscosity and electrophoretic test 2 hours after the protein liquid was exposed to sound. But in 5% albumin there was a change of value of osmotic pressure (osmolality) 20 hours later and after 30 hours there could be found a significant change (94 mOsm/kg $H_2O \rightarrow 108$ mOsm/kg H_2O) (Fig. 12). However, as for viscosity and electrophoretic test, distinct change could not be found (Fig. 13).

Discussion

As stated above, when strong energy is given to a solution of protein, its denaturation occurs. "Basic Chemistry" (Ogawa et al. 1953) made it clear already. In the process as far as denaturation I expected the ionization of amphoteric electrolyte and caught the ionization phenomenon as the change of volts. This probably means that the electric charge of

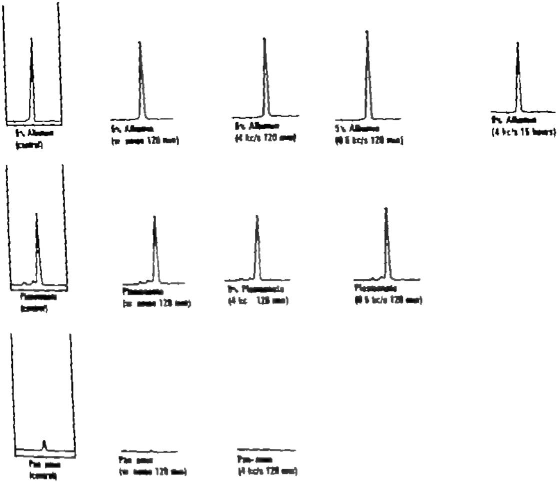

Fig. 13. Change in the electrophoretic test. The albumin curve began to fall from its peak 15 hours after the exposure to sound (right side).

(*d*) Denaturation test on the proteins

There was almost no change in osmotic pressure, viscosity and electrophoretic test 2 hours after the protein liquid was exposed to sound. But in 5% albumin there was a change of value of osmotic pressure (osmolality) 20 hours later and after 30 hours there could be found a significant change (94 mOsm/kg $H_2O \rightarrow 108$ mOsm/kg H_2O) (Fig. 12). However, as for viscosity and electrophoretic test, distinct change could not be found (Fig. 13).

Discussion

As stated above, when strong energy is given to a solution of protein, its denaturation occurs. Basic Chemistry (Ogawa et al. 1953) made it clear already. In the process as far as denaturation, I expected the ionization of amphoteric electrolyte and caught the ionization phenomenon as the change of volts. This probably means that the electric charge of

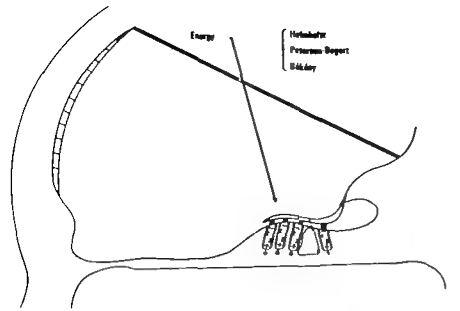

Fig 14 The hair cell model may be replaced by the inner ear in Fig. 14

positive and negative ions on the surface of the protein generates the flow of ions under the DC volts of 80 mV by giving the energy of oscillation to the protein through the vibrator But this phenomenon will be irreversible when the energy of oscillation lasts long and becomes strong, the particles of protein swell the viscosity increases the solubility decreases and the osmotic pressure increases My model is incomparatively bigger than the capacity of real hair cell in the inner ear It is a matter of course that the value of volts depends on the size of the model and the quality of the vibrator and the kinds of protein Therefore the functions of protein in the hair cells of the inner ear cannot be presumed through the results of this experiment But under a certain condition it is no doubt that a solution of protein can be ionized at least In 1954 Békésy assumed a transformer as a hair cell and the ionization of protein may be a reason And according to recent literature it is said that the troubles in the hair cells by ototoxic antibiotics of aminoglycoside group such as SM KM and so on are strongly effected by the denaturation of mitochondria in cells (Nakai et al 1971) It seems to me that it is in accord with the theory of basic chemistry which says these ototoxic antibiotics are the reactions stopping protein synthesis (Morino et al 1973)

Well what kind of relation does the quality of protein easily denatured by this kind of energy have with the trouble of the inner ear caused by sound and ototoxity? I will explain it in Chart 1

From the above-mentioned experiments

(1) It is supposed that the basal turn of cochlea receive strong energy by the structure and the quality of oscillation So the trouble caused by the exposure of sound and ototoxity is distinct in the basal turn

(2) Protein is ionized by the action of strong energy and when the action lasts long it is denatured Moreover it is presumed that this must be a close relation to audition vision thermesthesia and tactile sensation Next checking the change of pH there is a little tendency of transferring to alkali in albumin plasmanate and pan-amin I think this is because positive and negative ions of proteins are light electrolyte

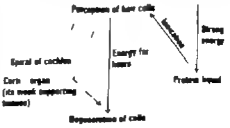

Chart 1

Summary

To catch the ionization of protein 105 phone energy of oscillation was given to 0.5 kc/s 4 kc/s and white noise exposed in 5% albumin plasmanate and pan-amin. I checked volts current, pH temperature and so on about them. Distinct change of volts was found in the albumin and the plasmanate which contained much protein. The value of volts stayed high for about 3 hours after they were stimulated, but with the passing of time it went down slowly. The model of hair cells may be replaced by the inner ear in Fig. 14.

From this phenomenon of ionization, I think I can presume the auditory mechanism of the hair cells of inner ear conversely. As for the denaturation of protein I noticed a change of osmotic pressure about 30 hours after they were exposed to sound. As mentioned above I think the action of energy which lasts long denatures protein and causes troubles in the inner ear (especially in basal turn).

Introduction

In the field of clinical laryngology indirect laryngoscopy is used as a routine method of examining patients Significant observations of the larynx can be obtained through this method including observations of the adductive and abductive movements of the vocal folds and of the arytenoids. Indirect laryngoscopy however has several shortcomings. It needs some skill on the part of the clinician and since the interpretation of the findings obtained by this method are more or less subjective diagnoses obtained by different laryngologists through indirect laryngoscopy alone may sometimes be inconsistent or even incompatible Pathologic changes beneath the true vocal folds are frequently overlooked The rapid vibratory motions of the vocal folds cannot be observed by conventional laryngoscopy Also there are certain patients on whom indirect laryngoscopy cannot be performed adequately because of an anatomical or a physiological abnormality or because of dyspnea.

In addition to indirect laryngoscopy direct laryngoscopy or special X-ray examinations such as laryngography may be used as supplementary methods for examining the larynx These supplementary methods however usually result in some discomfort or danger to the patient. Therefore a technique which can provide adequate laryngeal information with less discomfort or risk should be of significant help to clinical practice Diagnosis through the voices of patients, for example may fulfill this prerequisite because uttering voiced sounds can be done without any difficulty by most patients. Hence if it can be proved that voices of patients carry sufficient information for differentiating various laryngeal pathologies diagnosis by analyses of patients voices would be a useful supplement to indirect laryngoscopy

The voice can convey information other than meaning, such as sex, age and the emotional state of the utterer Furthermore in many cases an identification of the speaker may be made through speech As voice is a kind of sound it seems reasonable to assume that its basic perceptual characteristics are pitch loudness length and timber which correspond to known fundamental acoustical features. The overall number of perceptual cues seems to be rather limited Since man can recognize a variety of objects as mentioned above using a limited number of perceptual cues, it is quite possible that individual perceptual cues are used in recognition in different ways.

The acoustic characteristics of speech may be classified into two elements i e variable and invariable. For example while the possible maximum and minimum fundamental frequency of a person s voice is physiologically limited he can utter a voiced sound of any arbitrary frequency within this limit. The fundamental frequency of phonation here represents a variable element, while the upper or lower limit of the vocal range constitutes an invariable element. The same holds true with duration and intensity of voicing. Since the characteristics to be investigated for detecting laryngeal pathology should be invariable ele

ments that in abnormal acoustic features corresponding to certain pathologic changes in the larynx it may appear that such variable elements as fundamental frequency intensity duration etc are not distinctive cues for this purpose

Many investigators have therefore attempted to find invariable acoustic parameters which might correspond to laryngeal pathologies The parameters investigated have included the elevated levels of noise components and the loss of harmonic components in spectrograms of pathologic voices (Nessel 1960 Yanagihara 1967) increased pitch or frequency perturbation in acoustic waves of pathologic voices (Lieberman 1963 Smith & Lieberman 1964 Hiki et al 1967 Koike 1967 Iwata & von Leden 1970 Hecker & Kreul 1971) and information included in amplitude perturbation (Koike 1969) Although these studies provided considerable hope for the use of acoustic methods for detecting laryngeal lesions the results of these studies still seem to be insufficient for the purposes of categorization or of differential diagnosis of laryngeal diseases

On the other hand it is known that experienced laryngologists are to a considerable extent capable of diagnosing laryngeal diseases simply by listening to the voice of a patient There is a strong possibility that laryngologists are utilizing many acoustic parameters which have not yet been accounted for by the above mentioned acoustic studies when they make diagnosis of a laryngeal disease through use of a vocal cue

The terms for expressing the impressions of pathologic voices by laryngologists may be *hoarse harsh breathy* etc These terms however do not seem to be pertinent to differentiating laryngeal pathologies because the definitions of these terms are subjective and indistinct In order to elucidate the mechanism of diagnosing laryngeal diseases by voice therefore some perceptual studies seem to be needed and the use of precise psychometric procedures is required The methods relevant to this purpose may include paired comparison triadic comparison and the semantic differential techniques

Among these procedures the semantic differential technique proposed by Osgood et al (1957) has been utilized by several investigators for studying the auditory impression of human voice and speech Voiers (1964) found 4 perceptual factors from short speech samples from 16 men He labeled these factors as "clarity" or "intelligibility roughness "magnitude and "speech rate respectively Holmgren (1967) found that speakers voice characteristics can be accounted for by two basic factors as determined by listener judgments alone and referred to the factors as "loudness and pitch With the use of speech samples from 100 males and 100 females Silbiger (1966 1969) studied the perceptual classification of voices and reported that the analyses provided an excellent three-dimensional fit Besides he found that the ratings on the semantic differential represented the perception of the voice quality and were not dependent upon extraneous factors such as language difference Clarke & Becker (1969) extracted 4 factors from the spoken sentences of 8 male speakers By applying the semantic differential technique with 17 pairs of Japanese adjectives Isshiki et al (1969 1970) made a perceptual study of hoarseness They stated that analyses of the data with the use of D-factoring revealed 4 factors which they labeled as Factor R (rough) Factor B (breathy) Factor A (asthenic) and Factor D (degree) respectively Based on this result they proposed a simplified rating method for the classification of hoarseness

There have also been studies attempting to relate perceptual characteristics to certain acoustic properties of speech Emanuel & Sansone (1969) Sansone & Emanuel (1970) and Lively & Sansone (1970) for example tried to relate the auditory characters of simulated rough or harsh voice to spectral noise levels Wendahl (1963 1966*a b*) investigated the relations between pitch or amplitude per

turbation and perceptual impressions of synthesized voices. Coleman (1971) has studied the effect of waveform changes of simulated glottal waves upon the perception of roughness.

Although these studies have yielded some interesting results knowledge in this area still seems to be limited. It seems that there is an obvious need of conducting some perceptual studies in order to refine the procedures of judging voice quality in dealing with patients with laryngeal pathology and to relate the resulting perceptual cues to certain acoustic parameters which may be relevant to laryngeal pathologies It is hoped that this type of study will be of some help in ultimately establishing some diagnostics to supplement indirect laryngoscopy

The semantic differential technique was employed in the present study as a psychometric procedure because of its simplicity as in the cases of other studies described above Needless to say this selection does not imply that the semantic differential procedure is most appropriate for investigating the perceptual structure of voice quality It is rather apparent that this technique has some *limitations* Among others it should be noted that dimensions extracted with this technique are more or less dependent upon the pairs of words used to define the scales. Since this technique can provide an objective and accurate orthogonal basis for the data space nevertheless the adoption of the semantic differential technique seemed to be justifiable under certain conditions. A more powerful means of data collection and analysis may eventually prove useful, however in understanding the more detailed structure of speech perception

Method

A. SEMANTIC DIFFERENTIAL SCALES

1 English scales

As the scales for listener judgments 1 pairs of polar-opposite adjectives assumed to be most related to the judgment of voice quality were selected from the list of 50 pairs of words used by Osgood et al They were (1) nice–awful (2) sweet–sour (3) clean–dirty (4) happy–sad, (5) strong–weak, (6) large–small (7) heavy–light, (8) hard–soft, (9) fast–slow (10) active–passive (11) sharp–dull and (12) hot–cold

The first four pairs represented an *evaluation* factor the second four pairs a *potency* factor and the last four indicated an *activity* factor as described in the analysis of general concepts by Osgood et al. It should be mentioned however that these scales were selected rather arbitrarily and that there is no assurance that these scales are all pertinent to the perception of acoustic stimuli such as voice. A better selection of adjectives might be feasible in further study which may in turn explicate a more detailed structure of perception of pathologic voices. Also whether the factors derived from these scales correspond to such psychological characteristics as evaluation, potency etc is still to be determined

2. Japanese scales

In order to investigate the inter-cultural validity of this kind of study the 12 English scales were translated word-for word into Japanese adjective pairs They were (1) yoi–warui (2) amai–suppai (3) kireina–kitanai (4) shiawasena–fushiawasena, (5) tsuyoi–yowai (6) okii–chiisai (7) omoi–karui, (8) katai–yawarakai (9) hayai–osoi (10) sekkyokutekina–shokyokutekina, (11) surudoi–nibui, and (12) atsui–

– not measurable

tsumetai The same test stimuli were subjected to a separate listening test with the use of these Japanese scales

II TEST STIMULI

1 Voiced samples

The first set of stimuli consisted of samples of the vowel [a] tape recorded from 24 subjects 9 normal persons and 15 patients with various laryngeal diseases as shown in Table I There were 16 males and 8 females ranging in age from 11 to 76 After the speech recording was made the laryngeal status was derived by conventional indirect laryngoscopy In some cases surface anesthesia was needed

The subjects were instructed to sustain the vowel [a] for several seconds at the most comfortable pitch and loudness Magnetic tape recordings of the voices were obtained concurrently in two different ways The acoustic speech waveform from a dynamic microphone (Electrovoice 666) positioned in front of the subject s mouth was recorded on one channel of a dual channel tape recorder (Ampex AG 600-2) The acoustic signal from a small condenser microphone (Brüel & Kjaer 4136) coupled to the pretracheal skin of the subject was recorded on the other channel of the tape recorder The recorded acoustic speech wave form was employed for the listening tests while the recording from the pretracheal signal was used for the measurement of the acoustic parameters described below

From the voices recorded on the first channel segments of approximately 1 5 sec duration were chosen out of the most constant parts of the vowels Each of these segments was rerecorded 14 times at the same intensity on a separate tape recorder Approximately 2 5 sec of silence was given between the successive stimuli The intensities of the different voices were also adjusted to be the same As a result each voice sample used in

his study contained neither an initiation nor a termination and was almost constant. However some degree of fluctuation in both fundamental frequency and intensity within a sample was inevitable in some of the pathologic voices. The order of the presentation of the stimuli was randomized

The fundamental frequency (FF) a frequency perturbation quotient (FPQ) and an amplitude perturbation quotient (APQ) were analyzed from the contact microphone signals corresponding to the voice samples used for the listening tests. The FPQ was defined as an averaged and normalized perturbation of the peak-to-peak pitch periods. The frequency perturbation quotient is defined as

$$FPQ = \frac{\frac{1}{n-3}\sum_{i=2}^{n-2}\left|\frac{F_{i-1}+F_i+F_{i+1}}{3}-F_i\right|}{\frac{1}{n-1}\sum_{i=1}^{n-1}F_i}$$

where n indicates the number of period peaks and F represents the instantaneous frequency value defined as the inverse of the period length.

The APQ stood for a similarly averaged and normalized rate of variation in the peak amplitude It is defined to be

$$APQ = \frac{\frac{1}{n-11}\sum_{i=6}^{n-6}\left|\frac{A_{i-5}+A_{i-4}+\cdots+A_i+\cdots+A_{i+5}}{11}-A_i\right|}{\frac{1}{n-1}\sum_{i=1}^{n-1}A_i}$$

where A depicts the peak-to-peak amplitude of the fundamental period Detailed discussion on these acoustic parameters will be found elsewhere (Koike Takahashi & Calcaterra) The values of the acoustic parameters together with the laryngeal status age sex, and breathy and rough scores of the subjects are shown in Table I The explanation for the breathy and rough scores will be found below

2. Synthesized samples

The second set of stimuli consisted of synthesized vowel samples generated by a cascade type terminal analog synthesizer which was controlled by a PDP-8 digital computer A detailed description of this synthesis method is found elsewhere (Flanagan 1965) The frequencies of the first four formants were specified as 750 1250 2550 and 3000 Hz and their respective bandwidths were 60 80 100 and 200 Hz. A total of 9 samples having three different fundamental frequencies (100 Hz for low 205 Hz for medium and 300 Hz for high) at three different intensities separated by 5 dB steps (weak, medium and strong) were generated and recorded on a tape recorder (Ampex AG 600-2) Each sample was of 1.5 sec duration and was repeated 14 times at an interval of 2.5 sec.

C LISTENING TESTS

For the listening tests 6 different kinds of test sheets were prepared The 12 scales were randomized in terms of order and polarity The order of the sheets was also randomized for different listeners. This preparation was done for both the English and Japanese scales.

The listening tape was reproduced through a loud speaker (Ampex AA 620) in such a way that the same stimulus was repeated 14 times successively The sound pressure level of the stimulus at the listeners ears was approximately 75 dB re 0 0002 dyne/cm² The order of presentation of the different voices was randomly arranged in order to minimize the preoccupation of the subjects. Listeners rated their auditory impressions on the test tones against the 12 seven-point scales. During the course of instructions the listeners were asked to hear several repetitions of a sample However no further exercises were made before the rating task. Listeners were then requested to mark their first impression promptly

The listeners were selected from the laboratory staff who had normal hearing. In judging with the English scales 11 adults ranging in age from 23 to 41 including two females were adopted. Although they were scientists from various fields, none of them had notable ■

For the listening tests 6 different kinds of test sheets were prepared The 12 scales were randomized in terms of order and polarity The order of the sheets was also randomized for different listeners. This preparation was done for both the English and Japanese scales

The listening tape was reproduced through a loud speaker (Ampex AA 620) in such a way that the same stimulus was repeated 14 times successively The sound pressure level of the stimulus at the listeners ears was approximately 75 dB re 0 0002 dyne/cm² The order of presentation of the different voices was randomly arranged in order to minimize the preoccupation of the subjects. Listeners rated their auditory impressions on the test tones against the 12 seven-point scales During the course of instructions the listeners were asked to hear several repetitions of a sample. However no further exercises were made before the rating task Listeners were then requested to mark their first impression promptly

The listeners were selected from the laboratory staff who had normal hearing. In judging with the English scales, 11 adults ranging in age from 23 to 41 including two females were adopted. Although they were scientists from various fields none of them had notable ex

- = not measurable

tsumetai The same test stimuli were subjected to a separate listening test with the use of these Japanese scales

II TEST STIMULI

1 Voiced samples

The first set of stimuli consisted of samples of the vowel [a] tape recorded from 24 subjects 9 normal persons and 15 patients with various laryngeal diseases as shown in Table 1 There were 16 males and 8 females ranging in age from 11 to 76 After the speech recording was made the laryngeal status was derived by conventional indirect laryngoscopy In some cases surface anesthesia was needed

The subjects were instructed to sustain the vowel [a] for several seconds at the most comfortable pitch and loudness Magnetic tape recordings of the voices were obtained concurrently in two different ways The acoustic speech waveform from a dynamic microphone (Electrovoice 666) positioned in front of the subject s mouth was recorded on one channel of a dual channel tape recorder (Ampex AG 600-2) The acoustic signal from a small condenser microphone (Brüel & Kjaer 4136) coupled to the pretracheal skin of the subject was recorded on the other channel of the tape recorder The recorded acoustic speech wave form was employed for the listening tests while the recording from the pretracheal signal was used for the measurement of the acoustic parameters described below

From the voices recorded on the first channel segments of approximately 1 5 sec duration were chosen out of the most constant parts of the vowels Each of these segments was rerecorded 14 times at the same intensity on a separate tape recorder Approximately 2 5 sec of silence was given between the successive stimuli The intensities of the different voices were also adjusted to be the same As a result each voice sample used in

scribing the perceptual abnormality of patients voices in rather separate senses It was thought to be interesting to compare such clinical gradings with the semantic differential ratings on the same utterances. It should be mentioned, however that aside from the fact that these terms are most commonly used and widely understood by laryngologists they are merely examples and have been otherwise arbitrarily chosen from many expressions adopted in clinical descriptions. Many other selections should be feasible in future investigations.

D FACTOR ANALYSIS PROCEDURES

The data obtained were analyzed with either one of the two factor analytic methods Le D-method of factoring (Osgood et al 1957) and Lawley s maximum likelihood method (Lawley & Maxwell 1963) with Kaiser s varimax rotation (Kaiser 1958) Both methods were applied to some of the data (mainly those on natural voice samples) for comparison

In the following discussion, the word "dimension" will be used for the results of the D-method, while the word "factor" will be adopted for the results of the Lawley method

Results

A. RELIABILITY

Prior to the detailed analysis of the data, the reliability of the judgments was examined. As an indicator for dispersion of the rating score the square root of the unbiased variance or sample standard deviation (S D) was calculated for each scale for every voice Though the square root of the unbiased variance may not represent the strict inter listener reliability a small value should suggest a high degree of agreement among the listeners if the mean value is also taken into account Although there were certain judgments which revealed considerable S D values (for example 2.07 for P 1 on the strong–weak scale or 2 00 for P 5 on the heavy–light scale) most of the S D values were found to be in the range of 0.5 to 1.5 suggesting that the rating scores do indeed center closely around their mean values The agreement therefore seemed to be sufficient for the purpose of the present study

Test 1 and test were performed at an interval of 3 months which was thought to be a long period Six of the 8 listeners engaged in test 1 were also listeners for test 2. Since the voices of P 1 and P 5 were used in both tests, those 6 listeners rated their auditory impression on these selected pathologic voices on two occasions separated by a considerable time interval The correlation coefficient between the corresponding rating scores made

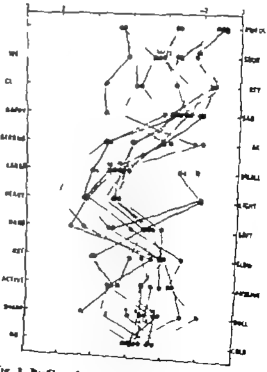

Fig 3 Profiles of mean rating scores for 10 pathologic voices on 12 adjective scales for test 3

perience in listening tests It seemed justifiable to regard them therefore as untrained naive judges In rating with the Japanese scales a group of 15 Japanese otolaryngologists who had no experience in listening experiments were employed They were all males between 26 and 41 in age but since they were pre dominantly in training in laryngology and did not yet have long-term experience with lis tening to pathologic voices they were also re garded as inexperienced naive listeners

A total of five listening tests were per formed The first four tests were on the Eng lish scales and the fifth was on the Japanese scales In the first test 8 listeners rated 5 pathologic voices (P 1 to P 5 in Table I) and one normal voice (N 1) In the second test 11 judges evaluated 8 normal (N 2 to N 9) and two pathologic (P 1 and P 5) voices The listeners were not notified in advance of the

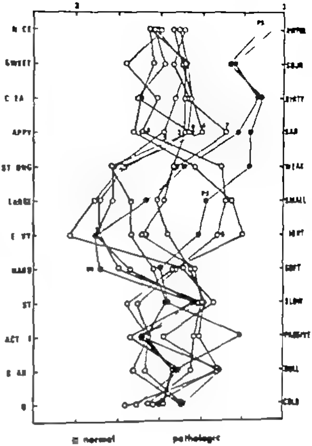

Fig 2 Profiles of mean rating scores for 8 normal and pathologic voices on 1 adjecti e scales for test –

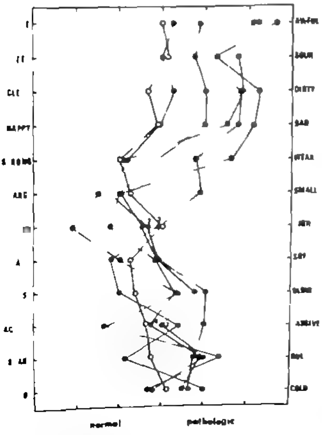

Fig 1 Profiles of mean rating scores for one normal and 5 pathologic voices on 1 adjective scales for test 1

tests that the stimuli included the signals pro duced by normal speakers In the third test 8 subjects judged 10 pathologic voices (P-6 to P 15) The synthesized samples were em ployed in the 4th listening test At the be ginning of this test the medium frequency" and medium intensity sample was presented 14 times as the reference sound The listeners however were not informed that the presenta tion was for reference Nine subjects per formed the rating task on English scales In the 5th test the 24 voice samples from the 15 pathologic and 9 normal subjects mentioned above were presented to the Japanese listeners and were rated in one listening session

In addition to the listening tests just de scribed two laryngologists evaluated all the voice samples in terms of breathiness and roughness These terms breathy and rough are most commonly employed in clinics for de

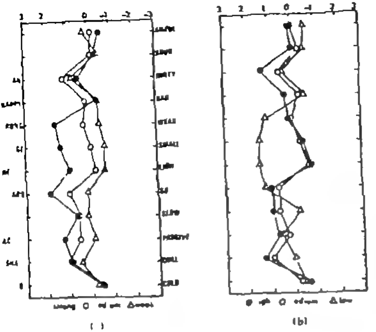

Fig. 5. (*a*) Profiles of mean rating scores for three synthesized samples with the same intensity. (*b*) Profiles of mean rating scores for three synthesized samples with the same fundamental frequency.

more than one perceptual dimension or factor might be related to these scales, in contrast to the case for the study of general concepts, since the score values for a given voiced sample varied from scale to scale.

The score values for the remaining 4 scales (fast–slow, active–passive, sharp–dull and hot–cold) also revealed complicated profiles for both normal and pathologic voices, though the degree of variation from the central line was rather limited. It was interesting to note that on the "hot–cold" scale the values for the normal voices fall mostly in the limited range on the left (hot) side of 0 (Fig. 2), while the scores for the pathologic stimuli cluster on the right (cold) side (Fig. 1, 2, and 3).

2. Synthesized samples

Figure 4 shows the profile for the 9 synthesized vowel samples. When this figure is compared with the profiles of the normal voices in Fig. 3, the following special features may be noticed. (1) All the samples except one are rated as very "clean" on the clean–dirty scale, though the ratings on the other 3 of the 4 initial scales were located close to the center line, as was the case for the normal voiced stimuli. (2) The profiles on the second group of scales are somewhat simpler in shape than those for the normal voices. (3) The profiles on the third group of scales except for the hot–cold scale tend to shift to the left (fast) side. (4) All the scores on the hot–cold scale concentrate on a limited area on the right (cold) side of the center. It may be said that the electrically synthesized vowels are rated to be "cleaner" and "colder" than the normal voices.

Fig. 5*a* shows a profile for the mean rating of the 3 samples that had the same intensity, and Fig. 5*b* illustrates the behavior of the samples which had the same fundamental frequency. It is seen in Fig. 5*a* that the scores shift to the left on the 4 second-group scales (strong–weak, large–small, heavy–light, and hard–soft) and on the "active–passive" scale in accordance with the increase in intensity. The other scales seem to be insensitive to the change in intensity.

The relation between the fundamental frequency and the averaged rating score seems to be somewhat more complicated than that be-

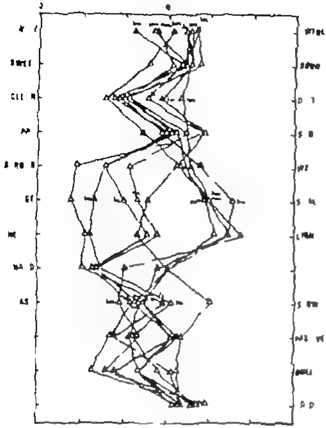

Fig 4 Profiles of mean rating scores for 9 synthesized vowel samples on 1 adjective scales for test 4

by the same 6 listeners for the two occasions was 0 86 Here again even though the cor relation coefficient may not strictly represent the test–retest reliability at any given level of significance it seemed to imply a tolerable replicability

II PROFILES OF THE SAMPLES ON THE SCALES

1 Voiced samples

Figures 1 2 and 3 depict the profiles of the mean rating scores on the adjective scales for tests 1 2 and 3 respectively The response to the normal voice stimuli can be seen in Figs 1 and 2 It is observed in Fig 1 that the scores for the normal subject do not greatly deviate from the central line while most of the pathologic profiles deviate considerably On the initial 4 scales (nice–awful sweet–sour clean–dirty and happy–sad) in particular the scores for the normal voice are all close to 0

This tendency can be seen in Fig 2 as well Although the values for normal voices in Fig. 2 vary considerably on some scales they show little variation from the middle line on the initial 4 scales It is interesting to note that the scores for each pathologic voice on these 4 scales is relatively constant for each voice As a result the profiles of all voices on these scales look almost vertical and parallel to the central 0 line The distance from the mid-line for these pathologic cases however is seen to vary from patient to patient depending upon the nature and degree of the pathology

This fact may indicate that these scales represent the same factor which is of an eval uative nature in the realm of perception of human voice as in the case of other general concepts studied by Osgood et al It was anticipated that there could be certain superior voices which would be rated as very nice very clean and so forth However almost all the normal voices were seen to cluster around the center line on these scales as mentioned above and no superior" rating was observed Similar results were described by Kreul & Hecker (1971) and by Levin et al (1961)

The scores for the 9 patients in test 3 also revealed essentially the same behavior on these 4 scales as shown in Fig 3 The considerable deviation from the central line seen in this figure seems to be attributable to the fact that this group included many advanced or serious cases with respect to the laryngeal status It should be noticed that most of the values were less than 0 i e the data located mainly on the right (awful) side

The scores for the voiced stimuli on the 5th 6th 7th and 8th scales (strong–weak large–small heavy–light and hard–soft) showed a remarkable variation as seen in Figs 1 2 and 3 It is noteworthy that the magnitude of such variation on these scales for the nor mal voices (as is observed in Fig 2) is almost equivalent to that for the pathologic utterances (as is demonstrated in Fig 3) The shapes of profiles for both normal and pathologic voices are quite complicated It was assumed that

Table II *Coordinate values on the dominant dimensions for tests 1 2 and 3*

Dimension	Voice

D-II-3	−188	−101	309	0	−200	356	−75	−238	−169	−70
D-III-3	43	0	−64	1	−129	−1	−151	198	−129	−71
D-IV 3	87	344	66	2	110	−1	75	103	99	179

sions were found for test 3 These dimensions will be referred to as D-I 1 D-I 2 D-I 3 D-II 1 etc., where the last digits 1 2, and 3 correspond to each test, the Roman numerals represent the dimension and the D refers to the dimension extracted by the D-method. Table II (parts *a* *b* and *c*) shows the coordinate values for each analysis. It is observed that in terms of the coordinate values the difference between the two pathologic voices that are common to tests 1 and 2 (P 1 and P 5) remains unchanged

The relationship between the extracted dimensions and the original rating scales was first studied Table III shows the correlation coefficients among the coordinate values on the dominant dimensions and the mean rating scores on the 17 scales. The variability of the extracted dimensions attributable to the difference in object (stimulus) group may be learned from this table since the main differences among tests 1 and 3 were those of stimulus structure

Table IV demonstrates the relationship among the extracted dimensions and the breathy score the rough score and the values of 3 acoustic parameters. The correlation coefficients among the different dimensions themselves are also shown in this table The data for voice P 15 were not included since acoustic analysis was not possible on this sample because of an extreme irregularity in the wave forms.

(a) Test 1 It is observed that dimension D-I 1 is correlated to the breathy score This dimension may be related to evaluating the character of voice especially in terms as "weak" "sad" etc and seems to be related to the loudness impression and also to evaluation The D-III 1 dimension is correlated to the fundamental frequency

(b) Test 2 The dimensions extracted from the data of test seem to be somewhat more complex than those from test 1 Dimension D-I 2 is seen to associate with the APQ and with both the breathy and rough scores. This dimension seems to be of an evaluative character Dimension D-II 2 is connected with such words as heavy" "large" etc. and reversely with the fundamental frequency Dimension D-III 2 is characterized by such words as slow hot etc. and is also inversely related to the fundamental frequency

tween the intensity and the mean score as is seen in Fig 5b The scores shift to the left side with the increase in fundamental frequency on the initial 4 scales (which seemed to be of an evaluative nature) The same holds true on the "fast–slow" and "sharp–dull" scales among the third group of scales On the second group of scales on the contrary the high pitched (300 Hz) or the medium pitched (205 Hz) samples are seen to deviate to the right side though these two kinds of samples did not reveal different profiles on this group of scales The low pitched stimuli (100 Hz) were apparently judged to be stronger larger and heavier than other samples The hot–cold scale seemed to be related neither to intensity nor to fundamental frequency

The results of test 5 in which 9 normal and 15 pathologic voices were rated on Japanese scales by Japanese laryngologists were found to be in very good agreement with the results shown in the figures for English scales As discussed later in a separate section further analyses confirmed this similarity and since they would therefore be redundant the results are not shown separately here

C RATING OF BREATHINESS AND ROUGHNESS

It is apparent that there exists considerable interaction between perceptions of breathiness and roughness judging from the regression in Fig 6 and from the significant correlation coefficient between them ($r=0.47$) It should be mentioned however that there are certain voices which were judged to be very rough yet not at all breathy It is evident that the concepts of breathiness and roughness involve certain different semantic contents though it seems to be clear that neither of these two concepts can be an entirely independent factor in the perceptual space

It should also be noticed that most normal voices were judged to be slightly rough or breathy No evident distinction could be observed between the normal and the pathologic

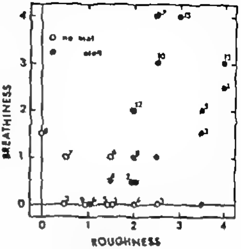

Fig 6 Scatter diagram of 24 voiced samples on the breathy–rough plane Each numeral attached to the circles indicates the sample number (see Table I)

voices in terms of these ratings The correlation coefficient between the two judges for these rating scores was 0 77 which was significant though this value was not considered to be high

D RESULTS OF FACTOR ANALYSIS

Section 1 D-method of factoring

The above mentioned rating scores were subjected to factor analyses The D-method of factoring yielded a series of coordinate values on the extracted dimensions for each stimulus The following criterion was adopted to determine whether or not a resulting dimension is dominant On each dimension extracted by this method the difference between the maximum and minimum was calculated For the ith dimension this value was called the range R_i If a dimension had an R_i value that was larger than 50% of the largest R_i (R_{max}) this dimension was defined to be dominant In most cases however the determination of the dominant dimensions was not difficult since the absolute coordinate values decreased rather sharply where dominant dimensions no longer existed

1 Voiced samples

Three dominant dimensions were extracted for both tests 1 and 2 and 4 dominant dimen

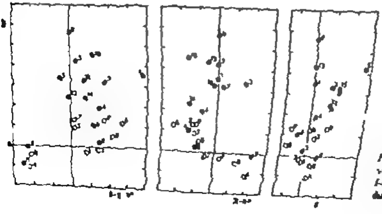
together When the factor analysis was made on the total data of 24 voiced stimuli 4 dominant dimensions were extracted For voices P 1 and P 5 the rating scores in test 1 were adopted. These dimensions will be referred to as D-I NP D-II NP etc. where N stands for "normal" and P for pathologic It should be mentioned however that some mathematical requirements for the statistical model may not be fulfilled for the analysis of such pooled data. The homogeneity of the data, for example cannot be guaranteed. The results of such an analysis therefore have to be carefully interpreted and should not be widely generalized

Table V shows the correlation matrix among the breathy and the rough scores the fundamental frequencies the frequency perturbation quotients, the amplitude perturbation quotients and the coordinate values on the D-I NP D-II NP D-III NP and D-IV NP dimensions for the 9 normal and 14 pathologic voices. P 15 was not included Table VI gives a set of correlation coefficients between the mean rating scores on the 17 scales and the coordinate values on the 4 perceptual dimensions for the total voiced samples.

It is understood from Tables V and VI that D-I NP is characterized mainly by such terms as awful" "sour" "dirty" etc and is correlated to both of the breathy and rough scores as well as to both of the FPQ and APQ This dimension evidently is of an evaluative nature D-II NP is associated with such terms as "large" heavy etc It seems reasonable to relate this dimension to loudness sensation D-III NP is connected with such terms as "sharp" "fast etc and is positively correlated to the FF This dimension is apparently related to pitch sensation.

D-IV NP is correlated with the breathy score and with the APQ and seems to be associated with the perception of breathiness It may be noted that the voices which reveal high values on this dimension i.e. P 1 P 5 and P 15 are from the patients with unilateral paralyses, and P 7 is a very breathy voice from a case having undergone partial laryngectomy



normal pathologic

Fig 7 Scatter diagram of 24 voiced samples on the I-II I-III and I-IV planes of dimensions.

Table III *Correlation coefficients between the coordinate values on the dominant dimensions a the mean rating scores on the adjective scales*

Dimension	Scales: Nice–awful	Sweet–sour	Clean–dirty	Happy–sad	Strong–weak	Large–small	Heavy–light	Hard–soft	Fast–slow
D-I 1	−0 75	−0 94	−0 75	−0 67	−0 1	0.37	0.87	0 14	−0 42
D-II 1	−0 79*	−0 48	−0 81	−0 85	−0 98	−0.37	−0 14	−0 09	−0 70

D-III-S	−18	2	3	−4	−6	134	0	17	29

same fundamental frequency. It is seen in this figure that the first dimension D-I S is related to the intensity, i.e. the "stronger" samples consistently have larger coordinate values than the "weaker" samples and vice versa. Similarly D-II S is apparently related to the fundamental frequency. It is presumed that the dimension associated with evaluation did not reveal itself as a dominant dimension because the quality of the synthesized stimuli was controlled to be the same except for the fundamental frequency and the intensity. This may also be predicted from the profiles of these samples on the first group of adjective scales.

3 *Additional analysis*

The factor analysis was also carried out on the combined data of the normal and the pathologic voices together with the synthesized vowel samples as a reference. Because of a space limitation in the computer used for the analyses however the data of only 4 of the 9 normal voices (N-4 to N 7) and 6 of the synthesized samples (three "high"s and three "low"s) were added to those of the 15 pathologic voices. Four dominant dimensions were extracted. Figure 9 demonstrates the location of the samples on the I II, I III and I IV planes. These dimensions are referred to as D-I NPS, D-II NPS etc. It is apparent that the direction of the extracted dimensions varies considerably by adding or altering the data, as can be seen by comparing the location of each point in Fig. 7 or in Fig. 8 with that in Fig. 9.

nevertheless, are seen to correlate with such major characteristics as evaluation loudness and pitch though which dimension cor responds to which character has to be ex amined each time

The 4 dominant factors extracted by Isshiki et al (1969) with the use of the same procedure as ours should correspond to the dimensions discussed above. Although they named their factors "rough" (R) "breathy" (B) "asthenic" (A) and "degree" (D) respectively such a labeling has no tenable basis and is misleading. Further the orientation of such factors will vary for different sets of stimuli

for the reason mentioned above) Table VIII displays the 15×15 correlation matrix This matrix was then subjected to the Lawley s maximum likelihood analysis and was rotated by the varimax method in order to obtain a simple orthogonal structure Table IX represents the results

2 *On Japanese scales*

The same analysis procedure was repeated on the data obtained with the use of Japanese scales and Japanese listeners as in the case of English scales The results are given in Table X

Discussion

A DIMENSIONS EXTRACTED BY D-METHOD FACTORING

The profiles of the data from tests 1 2 and 3 reveal particularly when they are compared with those from test 4 that certain acoustic features such as the fundamental frequency and intensity of the stimuli do affect the perceptual judgments on the adjective scales adopted A considerable shift on the scales observed both in normal and pathologic samples seems to be mostly attributable to the differences in such basic features rather than to some particular pathologic characteristics of the stimulus voices It is quite probable that certain combinations of such basic characters as fundamental frequency or intensity are playing some complicated roles in judging the voice quality

It is also noteworthy that there is a certain cue which is evidently associated with the evaluation of the degree of voice abnormality The factor represented by the first 4 pairs of words for example reveals appreciable dispersions only for the pathologic stimuli This perceptual mechanism obviously works when the stimuli include some pathologic utterances

The D-method of factoring typically reveals 3 or 4 dominant dimensions associated with evaluation loudness and pitch as mentioned above Since the orientation of the dimensions with this analysis method is determined by the particular set of data under analysis any change in the data structure will result in an alteration of the direction of the dimensions This is evidently recognized from the results of tests 1 2 and 3 The resulting dimensions

nevertheless, are seen to correlate with such major characteristics as evaluation, loudness and pitch, though which dimension corresponds to which character has to be examined each time.

The 4 dominant factors extracted by Isshiki et al. (1969) with the use of the same procedure as ours should correspond to the dimensions discussed above. Although they named their factors "rough" (R), "breathy" (B), "asthenic" (A) and "degree" (D) respectively, such a labeling has no tenable basis and is misleading. Further, the orientation of such factors will vary for different sets of stimuli

*significant.

The classification of hoarseness based upon such undefined factors has to be inherently quite arbitrary and subjective

It is seen in *Fig 9* that there exist several clusters of pathologic voices in terms of the D-I NPS dimension (which is highly correlated with D-II NP and is associated with loudness sensation) For example P 1 and P 13 which have similar coordinate values on the ordinate are the voices of pre and post-operative laryngeal cancer respectively The voices of patients with unilateral paralysis i e P 3 P 5 and P 15 have similar coordinate values on this axis These two groups are well separated on this dimension On the other hand on D-III NPS (which is highly correlated with D-III NP and is connected with pitch sensation) most of the pathologic voices have similar coordinate values on the low pitched side It seems to be reasonable therefore to suppose that certain combinations of the perceptual dimensions corresponding to pitch loudness or evaluation are to a considerable extent related to the auditory categorization of laryngeal diseases as mentioned earlier in this section

B THE FACTORS EXTRACTED BY THE MAXIMUM LIKELIHOOD METHOD

It is observed in Table IX that F I (the first factor) extracted by Lawley s Maximum Likelihood Method is characterized by such terms as "awful" "sour" and dirty and is correlated reversely with the FPQ and APQ This factor seems to be of evaluative nature as in the case of the D-I NP extracted by the D-method F II reveals relationship to fast light" "sharp and some other terms and is seen to correlate with fundamental frequency This factor evidently is connected with pitch sensation F III demonstrates significant coefficients with "strong" and "large" and is apparently related to loudness sensation F IV is associated only with "hard" at one extreme

It is interesting to note that some of these

Table XI *Correlation matrix of the 4 factors extracted by the maximum likelihood method*

	F-II	F-III	F IV
F I	−0 00	0 00	0.01
F II		−0 02	0.03
F-III			0.00

factors showed evident relationships with certain acoustic measures studied A very high correlation value (0 91) between the APQ and F I (which seems to be evaluative) in Table IX for example seems to be particularly noteworthy This figure implies that over 80% of the variances associated with this axis can be accounted for by the APQ In other words the APQ may have been a tangible acoustic correlate to this dimension This tendency is also recognized from the results of the D-method where the correlation coefficient between the D-I NP and the APQ reached 0 86 which was the highest value in Table V

Similarly F II revealed a high correlation coefficient (0 83) with the fundamental frequency The same held true with the relationship between the D-III NP and the FF (0 83) Here again most (69%) of the variances could be accounted for by this correlate

Since the intensities of the stimuli were adjusted to be the same except for the synthesized samples the effects of the intensity upon the factors have to be examined in directly from the results of synthesized stimuli It seems rather apparent nevertheless that F III is strongly related to the intensity though the judgment of the intensity (or "loudness in a psychological sense) would have been based more on some other features such as the sensation of vocal effort than on the actual intensities of the stimuli

The acoustic correlate to F IV has not become clear from the present data. D-IV NP however was seen to correlate with the breathy score and with the APQ It is believed that the factors such as the F IV or the D-IV NP should not be neglected when minor per

ceptual differences among pathological voices are to be studied, even if a definite acoustic correlate has not yet been explicated.

C. COMPARISON OF THE RESULTS OBTAINED BY DIFFERENT FACTOR ANALYTIC METHODS

There exists an apparent similarity between the result of the D-method and that of Lawley's method with varimax rotation. The first 3 dimensions from the D-method and the initial 3 factors extracted by the Maximum Likelihood Method are quite alike. They related to "evaluation", "loudness" and "pitch", respectively. A major difference between the two kinds of results may be the fact that the dimensions extracted by the D-method are not necessarily independent from each other as shown in Tables IV and V while the factors extracted by the Maximum Likelihood Method are quite independent as shown in Table XI. For example, the D-II NP (which is related to loudness) was correlated with the D-III NP (which is related to pitch) and with fundamental frequency. No significant correlation was found, on the other hand, between the F III (associated with loudness) and the F II (connected with pitch).

This discrepancy between the two methods may be understandable from the fact that the D-method always extracts the dimensions orthogonal to each other and no rotation of the dimensions was made to find a better fit to the underlying perceptual dimensionality which may not be necessarily of orthogonal structure. This particular feature of the D-method of factoring should be kept in mind when an interpretation of the results of an analysis with this method is attempted.

D. COMPARISON OF THE DATA OF ENGLISH SCALES AND THOSE OF JAPANESE SCALES

By comparing the results in Table IX with those in Table X, the effect of language environments upon the same set of voice stimuli may be studied. Here again, the nature of the first three factors are very similar, even though the order of F II and F III is reversed. In other words, even though the judges and the language environments were different, a similar result was obtained for the same voice samples as far as the first three factors are concerned. This fact may indicate that, even if there exist subtle differences in meaning between the corresponding scales in Japanese and in English, the perceptive impressions on the same stimuli remain much the same in a relative sense. That is, the perceptual space for the voice quality may not be appreciably affected by the intercultural differences.

E. SOME ADDITIONAL COMMENTS

Although not much emphasis was placed on this point in the present study, the question of the number of dominant dimensions for different sets of stimuli seems to be quite interesting. Our results on the synthesized vowels strongly suggest that for certain stimuli the perceptual dimensions may be less in number than on some other occasions. It is likely, for example, that the dimensions required for the perception of *normal* voices are only three and that such a three-dimensional space forms a sort of subspace in a more complicated perceptual space that also includes various different pathological voices.

It should be mentioned also, that the voiced samples used in the present study were merely some short segments excerpted from the steady-state portions of sustained vowels which contained neither the vowel initiations nor the terminations. The initial and the terminal parts of the voice may carry abundant information not contained in the steady states. Also, the intensities of the voice stimuli were adjusted to be the same in this study. There should be an apparent variation in the overall intensity for different patients. Further, an abrupt transient occasionally observed, such

The classification of hoarseness based upon such undefined factors has to be inherently quite arbitrary and subjective

It is seen in Fig 9 that there exist several clusters of pathologic voices in terms of the D-I NPS dimension (which is highly correlated with D-II NP and is associated with loudness sensation) For example P 1 and P 13 which have similar coordinate values on the ordinate are the voices of pre and post-operative laryngeal cancer respectively The voices of patients with unilateral paralysis i e P 3 P 5 and P 15 have similar coordinate values on this axis These two groups are well separated on this dimension On the other hand on D-III NPS (which is highly correlated with D-III NP and is connected with pitch sensation) most of the pathologic voices have similar coordinate values on the low pitched side It seems to be reasonable therefore to suppose that certain combinations of the perceptual dimensions corresponding to pitch loudness or evaluation are to a considerable extent related to the auditory categorization of laryngeal diseases as mentioned earlier in this section

II THE FACTORS EXTRACTED BY THE MAXIMUM LIKELIHOOD METHOD

It is observed in Table IX that F I (the first factor) extracted by Lawley s Maximum Likelihood Method is characterized by such terms as "awful sour and dirty and is correlated reversely with the FPQ and APQ This factor seems to be of evaluative nature as in the case of the D-I NP extracted by the D-method F II reveals relationship to "fast" light sharp and some other terms and is seen to correlate with fundamental frequency This factor evidently is connected with pitch sensation F III demonstrates significant coefficients with "strong and large" and is apparently related to loudness sensation F IV is associated only with hard' at one extreme

It is interesting to note that some of these

Table XI *Correlation matrix of the 4 factors extracted by the maximum likelihood method*

	F II	F III	F-IV
F I	−0 00	0.00	0 01
F II		−0 02	0 03
F III			0.00

factors showed evident relationships with certain acoustic measures studied A very high correlation value (0 91) between the APQ and F I (which seems to be evaluative) in Table IX for example seems to be particularly noteworthy This figure implies that over 80% of the variances associated with this axis can be accounted for by the APQ In other words the APQ may have been a tangible acoustic correlate to this dimension This tendency is also recognized from the results of the D-method where the correlation coefficient between the D-I NP and the APQ reached 0 86 which was the highest value in Table V

Similarly F II revealed a high correlation coefficient (0 83) with the fundamental frequency The same held true with the relationship between the D-III NP and the FF (0 83) Here again most (69%) of the variances could be accounted for by this correlate

Since the intensities of the stimuli were adjusted to be the same except for the synthesized samples the effects of the intensity upon the factors have to be examined indirectly from the results of synthesized stimuli It seems rather apparent nevertheless that F III is strongly related to the intensity though the judgment of the intensity (or "loudness in a psychological sense) would have been based more on some other features such as the sensation of vocal effort than on the actual intensities of the stimuli

The acoustic correlate to F IV has not become clear from the present data. D-IV NP however was seen to correlate with the breathy score and with the APQ It is believed that the factors such as the F IV or the D-IV NP should not be neglected when minor per

war mit der Stärke der dritte mit der Grundfrequenz der Reizmittel verbunden Ausser den drei vorherrschenden Faktoren stellten sich auch einige unbedeutendere Faktoren bei der Unterscheidung pathologischer Stimmen als wichtig heraus.

as a voice break often gives an important clue to the laryngologist There seem to be many acoustic and perceptual characteristics which remain to be studied

F CONCLUDING REMARKS

It seems justifiable to mention that the perceptual space for voice quality does have a multi-dimensional structure There seem to be 4 dominant dimensions corresponding to amplitude perturbation to fundamental pitch to intensity and to some undetermined acoustic feature respectively though the exact direction observed for each dimension depends upon the set of auditory stimuli given It was suggested that the perception of certain types of voices may be based on a simpler space with a smaller number of dimensions forming a kind of subspace within the entire 4-dimensional space of auditory perceptions Two different methods of factor analysis revealed essentially the same result as stated above. It was also suggested that the perceptual space for voice quality is not remarkably affected by different language environments

Summary

Perceptual criteria for classifying pathologic voices in comparison with normal voices were studied with the use of the semantic differential technique using 12 pairs of polar opposite adjectives The factors extracted from the data by means of the D-method and of the maximum likelihood method were correlated to fundamental frequency a frequency perturbation quotient and an amplitude perturbation quotient The utterances produced by 9 normal and 15 pathologic subjects together with 9 synthesized vowel samples were investigated The first factor was related to evaluation of voice quality and was also closely related to the amplitude perturbation. The second and the third factors were associated with intensity and fundamental frequency of the stimuli respectively Some minor factors other than the three dominant factors were also supposed to be relevant to the distinction of pathologic voices

Zusammenfassung

Wahrnehmbare Kriterien zum Einordnen von pathologischen Stimmen im Vergleich zu normalen Stimmen wurden unter Gebrauch der semantischen Unterscheidungsmethode untersucht die zwölf Paare polar entgegengesetzter Adjektive verwendete Die aus den Resultaten vermittels der D" Methode und der Höchstwahrscheinlichkeitsmethode entnommenen Faktoren wurden in Wechselbeziehung zur Grundfrequenz zum Grundfrequenzstörungsquotienten und zum Amplitudenstörungsquotienten gebracht Die Ausserungen von neun normalen und fünfzehn pathologischen Versuchspersonen so wie neun zusammengesetzte Vokalproben wurden untersucht Der erste Faktor war auf die Bewertung der Stimmeigenschaft gerichtet und stand auch in Beziehung zur Amplitudenstörung. CONTENTS

Introduction

Meniere's disease, so named by Simon Duplay (1872), has been recognized as a clinical entity for over a century. The original paper by Meniere describing the disease entitled "Memoire sur des Lesions de L'Oreille Interne Donnant Lieu a des Symptomes de Congestion Cerebrale Apoplectiforme" was published in 1861. The paper was translated from the original into English by Atkinson in 1961 and into Spanish by Velasco in 1968.

Although the disease has been a well known entity since 1861 and many methods of treating the condition have been proposed, its etiology and pathophysiology have not been precisely determined. The purpose of this paper is to review the histopathology of Meniere's disease in twenty-five temporal bone specimens of twenty individuals and to correlate the pathological changes with the clinical findings.

I Review of the Literature

LIGHT MICROSCOPY FINDINGS

The first description of the histopathology of Meniere's disease was made by Hallpike & Cairns in 1938 from temporal bone specimens of two patients who had died following surgical procedures for partial section of the VIII cranial nerve. One of these individuals had suffered from symptoms of the disease for three years and the other for five years. The most significant finding was dilatation of the endolymphatic systems, an observation which has subsequently been confirmed in numerous further studies. Hallpike & Cairns also described degenerative changes in the organ of Corti and "absence of the normal area of perisacular connective tissue" in the area of the endolymphatic sac. One ear also showed degeneration of the stria vascularis. They termed the condition "Hydrops Labyrinthi".

Yamakawa (1938) is credited with the second report on the pathology of Meniere's disease although the cases he presented were poorly documented. In 1940, Hallpike added a third case showing hydrops, but in which the sensory and neural elements and stria vascularis were normal. Subsequently, cases with prolonged clinical histories and without evidence of degenerative changes have been reported (Altmann & Fowler Jr 1943). Most authors agree that atrophy of the sense organ can occur in exceptionally severe cases (Kristensen 1961, Lindsay 1967, Schuknecht 1968 a).

In 1958, Lindsay described a temporal bone showing *only cochlear hydrops*, and in 1942, he described what he called herniations consisting of ballooning out of weak spots in the superior labyrinth. Altmann & Kornfeld (1965) referred to these as out-pouchings to differentiate them from other types of disruption of the labyrinthine membranes. They described the distortions of the labyrinthine walls as either distentions of the membranes, in which the walls "show the same appearance as the remainder of the structure they are derived from" or "circumscribed thin walled out-pouchings". They suggested that the pathogenesis of the out-pouchings was either

specific change other than that which would be expected to occur as the result of aging

ANIMAL STUDIES

Even before the discovery of endolymphatic hydrops as the principal pathological finding in Meniere s disease research was being performed on the endolymphatic system In 1921 Portmann produced vestibular disturbances in the fish Leiobatus Postinaca by sealing the endolymphatic duct McNally (1926) failed to reproduce similar disturbances in the rabbit by applying pressure and cautery to the endolymphatic sac Guild (1927) injected dye into the basal turn of the cochlear duct of the guinea pig and recovered it in the endolymphatic sac providing the first evidence that the sac might play a role in the physiology of the endolymphatic system

Lindsay (1947) obliterated the endolymphatic sac and duct of the monkey (Macacus Rhesus) but failed to produce changes in the volume of endolymph thus concluding that in the monkey the maintenance of a normal quantity of endolymph does not depend on the endolymphatic sac.

Altmann & Waltner (1947) while using rabbits found that the injection of iron salt solution into the cerebrospinal fluid reached the perilymphatic spaces through the cochlear aqueduct and then passed through Reissner s membrane into the cochlear duct to be absorbed by the stria vascularis These same authors (1950) repeated the experiment in rabbits and monkeys and concluded that the endolymph is resorbed in the stria vascularis and only "substances which are difficult for resorption by the regular cochlear mechanism are carried to the sac where they are broken up by the phagocytes and eventually resorbed"

Lindsay et al (1952) Schuknecht & Kimura (1953) van Egmond & Brinkman (1956) Schuknecht & Seifi (1963) and others performed ablation studies on the endolymphatic sac but none were clearly able to produce endolymphatic hydrops.

Naito in 1959 and Kimura & Schuknecht in 1965 succeeded in producing endolymphatic hydrops by obliteration of the endolymphatic sacs while working with guinea pigs In 1968 Schuknecht achieved the same results in cats These studies showed for the first time that the endolymphatic sac plays an important role in fluid physiology of the inner ear

In guinea pigs the endolymphatic hydrops occurred within two weeks of blocking the endolymphatic duct while in cats definite hydrops could only be found after survival times of two to three years Thus it became clear that previous failures to produce hydrops in cats were due to the short post ablation survival times These and subsequent studies have also shown that loss of the endolymphatic sac function not only produces hydrops but also degenerative changes in the organ of Corti and cochlear neurons more severe in the apices of the cochleae (Schuknecht & Kimura 1953)

II Histopathologic Findings in the Labyrinthine Membranes

MATERIAL AND METHOD

This report is based on the study of twenty five temporal bones from twenty individuals with Meniere s disease The disease was unilateral in fifteen and bilateral in five All patients had histories consistent with Meniere s disease The temporal bones were removed with the bone plug cutter from two to twenty-four hours after death, placed in formaldehyde and heidenhain susa solution

rupture of the inner wall of the labyrinth with ballooning out of the outer layer or atrophy of both layers in restricted regions with herniations into the perilymphatic space

Lawrence & McCabe (1959) reported healed ruptures in Reissner s membrane and Schuknecht (1962) described healed disruptions in the utricle and semicircular canals

Lindsay (1960) believed that rolled up margins in areas of complete discontinuity or rupture of the membranes indicated ante mortem changes and not artifact Altmann & Kornfeld (1965) because they found it difficult to believe that two ruptures could occur in the same structure doubted the validity of this interpretation

Two temporal bones have been described with fistulae between the utricle and saccule (Altmann & Fowler 1943 Kristensen 1961) Both were found in individuals with long standing disease and severe symptomatology Hallpike & Cairns (1938) and Altmann & Fowler (1943) described blebs on the membranous labyrinths of ears exhibiting the hydrops of Meniere s disease Lempert (1952) found them in surgical specimens removed during labyrinthectomy and termed them vesicular epithelial excrescences He believed them to be a sign of chronic progressive degenerative changes and suggested that they might be responsible for the endolymphatic hydrops These excrescences are also known to occur in normal specimens and therefore cannot be associated specifically with Meniere s disease

Degenerative changes in the epithelium of the endolymphatic sac have been described by Hallpike & Cairns (1938) and Hallpike & Wright (1940) and more recently by Gussen (1971) and Arenberg et al (1971) However these changes do not seem to be consistently present in ordinary light microscopic preparations (Yuen & Schuknecht 1972)

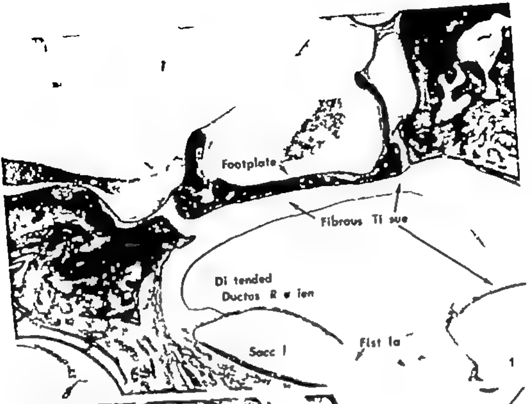
In 1968*a* Schuknecht described a formation resembling choroid plexus in the region of the ductus reuniens in several ears of individuals with Meniere s disease He thought that although these formations were not consistently found they might have a secretory function and thus be of pathogenic significance in the development of endolymphatic hydrops. In a more recent report Gussen (1971) found a similar formation in the intermediate portion of the endolymphatic sac in one ear with endolymphatic hydrops She then reviewed 170 normal specimens and found only one such structure In the same report she described anomalies of the membranous crus commune and the bony endolymphatic duct She concluded that Meniere s disease can either be idiopathic or secondary to these anomalies

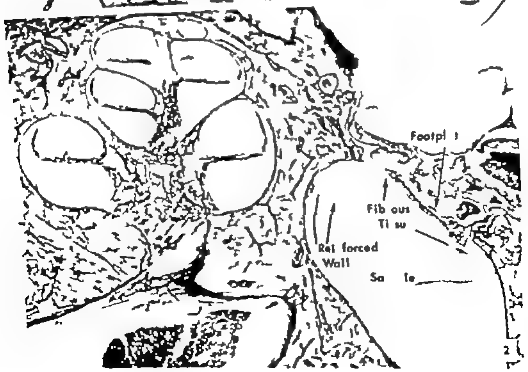
ELECTRON MICROSCOPY FINDINGS

The use of electron microscopy in the study of Meniere s disease is complicated by the inaccessability of the membranous labyrinth However removal of tissue during surgical procedures (e g labyrinthectomy) has provided some specimens for study

Peitrantoni & Iurato (1960) in a study of one crista ampullaris found vacuolization cytoplasmic inclusions of unknown nature and absence of cilia in the sensory cells They also noticed vacuolization and vesicles in the supporting cells Litton & Lawrence (1961) Friedmann et al (1963) and Ireland & Farkashidy (1963) showed similar findings in surgical specimens In a more recent report Hilding & House (1964) studied specimens of membranous labyrinth removed from ears with acoustic neuromas and found similar changes suggesting that the alterations might be due to surgical trauma. They concluded the vacuolizations were more frequent in Meniere s ears but stated that it is not possible to say at this time whether this change is a fixation artifact change of age reaction to toxin or some combination of these factors

Kimura & Schuknecht (1970a 1970b) examined the stria vascularis in surgical specimens and also failed to recognize any





F *1* (Case) Distended ductus reuniens occupying much of the vestibule. There is an endolymph-to-endolymph fistula between the saccule and the distended ductus reuniens.

Fig 2 (Case E W not included in the volumetric study) Distended saccule ith fibrous tissue proliferation under the footplate of the stapes and lateral all of the vestibule

decalcified in trichloroacetic acid solution and embedded in celloidin All specimens were sectioned at a thickness of 20 μm and every tenth section stained with hematoxylin and eosin and mounted on glass slides (Schuknecht 1968*b*)

Special care was taken to cut the horizontal sections in the plane of the modiolus of the cochlea in order to facilitate graphic reconstruction of the sensory and neural elements of the cochlea and stria vascularis (Guild 1921 Schuknecht 1953) Of the twenty five ears with Meniere s disease eighteen were in an excellent state of histological preservation and preparation and therefore suitable for detailed histological study and graphic reconstruction Only part of one other specimen (Fig. 45) was suitable for study In the fifteen individuals with unilateral Meniere s disease the opposite ear was available and suitable for study and detailed graphic reconstruction in six

1 The inferior labyrinth (Cochlea and saccule)

Membrane dilation

Dilation of the cochlear duct is present in all nineteen specimens Several show collapse presumably following previous dilation Although herniation of Reissner s membrane through the helicotrema has been frequently described in the literature (Hallpike 1938 Rollin 1940 Lindsay 1942 1944 1960 and 1967 Kristensen 1961 Altmann 1965 Kohut 1972 Blättler et al 1973) this finding is present in only two of the nineteen specimens (Figs 33 and 43) Four others (Figs 35 36 40 and 41) however show nearly complete filling of the scala vestibuli in the apical region by the distended cochlear duct and five cochleae (Figs 33 35 37 42 and 43) show almost complete filling of the scala vestibuli by the cochlear duct at points other than the cecum vestibulare

Herniation into the vestibule of the cecum vestibulare of the cochlear duct or ductus reuniens as previously described by Schuknecht (1962) and Altmann (1965) is present in eight ears (Figs 30 31 35 38 39 42 44 and 45) One of these shows a fibrous adhesion between the herniated membrane and the footplate and lateral wall of the utricle (Figs 1 and 31)

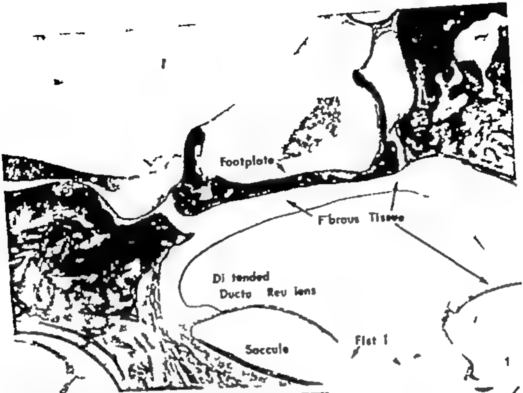
The saccule is dilated in all the specimens. One ear shows only mild dilation of the saccule and cochlear duct (Fig 29) In nine ears the saccular wall is in contact with the stapes footplate (Figs 32 33 34 35 36 38 40 41 and 43) with three showing fibrous adhesions to the footplate (Figs 33 34 41) (See Fig 2) In specimen sixteen the distended saccular wall also lies in contact with a distended cochlear duct In two ears (Figs 38 and 45) the enlarged saccule extends into the nonampulated end of the lateral semicircular canal a condition previously described by Altmann (1943) Lindsay (1944) Day (1949) Altmann (1965) and Lindsay (1967) (Fig 3)

In most specimens the reinforced area of the saccular wall retains its normal position suggesting that it is more resistant to distortion by the effects of the endolymphatic hydrops (Fig. 4)

Membrane collapse

It is not always possible to determine whether collapse of labyrinthine membranes represents postmortem or antemortem changes as pointed out by Schuknecht (1968*c*)

Membranes which are distended and thus possibly weakened may be more susceptible to preparation artifacts A good example of antemortem collapse is seen in ear four which has a collapsed but previously distended cochlear duct In the collapsed lumen there is acidophilic fluid and precipitate (Figs 5 and 6) Ears two and four (Figs 28 and 30) show partially collapsed saccular walls and ear nine (Fig. 35) shows a previously distended cochlear duct which appears to have been compressed and collapsed against the foot



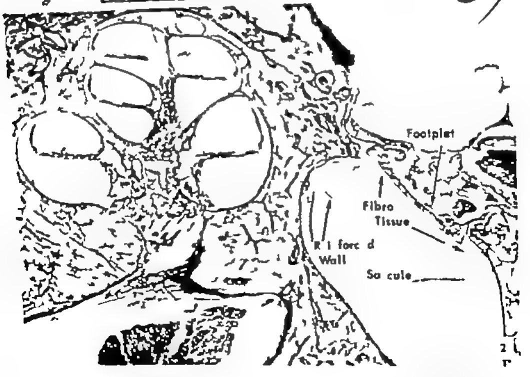


Fig. 1. (Case) Distended ductus reuniens occupying much of the vestibule. There is an endolymph-to-endolymph fistula between the saccule and the distended ductus reuniens.

Fig. 2. (Case E. W., not included in the volumetric study) Distended saccule with fibrous tissue proliferation under the footplate of the stapes and lateral wall of the vestibule.

decalcified in trichloroacetic acid solution and embedded in celloidin All specimens were sectioned at a thickness of 20 μm and every tenth section stained with hematoxylin and eosin and mounted on glass slides (Schuknecht 1968*b*)

Special care was taken to cut the horizontal sections in the plane of the modiolus of the cochlea in order to facilitate graphic reconstruction of the sensory and neural elements of the cochlea and stria vascularis (Guild 1921 Schuknecht 1953) Of the twenty five ears with Meniere s disease eighteen were in an excellent state of histological preservation and preparation and therefore suitable for detailed histological study and graphic reconstruction Only part of one other specimen (Fig. 45) was suitable for study In the fifteen individuals with unilateral Meniere s disease the opposite ear was available and suitable for study and detailed graphic reconstruction in six

1 The inferior labyrinth (Cochlea and saccule)

Membrane dilation

Dilation of the cochlear duct is present in all nineteen specimens Several show collapse presumably following previous dilation Although herniation of Reissner s membrane through the helicotrema has been frequently described in the literature (Hallpile 1938 Rollin 1940 Lindsay 1942 1944 1960 and 1967 Kristensen 1961 Altmann 1965 Kohut 1972 Blättler et al 1973) this finding is present in only two of the nineteen specimens (Figs 33 and 43) Four others (Figs 35 36 40 and 41) however show nearly complete filling of the scala vestibuli in the apical region by the distended cochlear duct and five cochleae (Figs 33 35 37 42 and 43) show almost complete filling of the scala vestibuli by the cochlear duct at points other than the cecum vestibulare

Herniation into the vestibule of the cecum vestibulare of the cochlear duct or ductus reuniens as previously described by Schuknecht (1962) and Altmann (1965) is present in eight ears (Figs 30 31 35 38 39 42 44 and 45) One of these shows a fibrous adhesion between the herniated membrane and the footplate and lateral wall of the utricle (Figs 1 and 31)

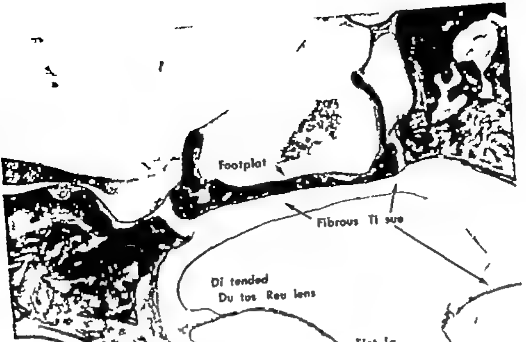
The saccule is dilated in all the specimens One ear shows only mild dilation of the saccule and cochlear duct (Fig 29) In nine ears the saccular wall is in contact with the stapes footplate (Figs 32, 33 34 35 36 38 40 41 and 43) with three showing fibrous adhesions to the footplate (Figs 33 34 41) (See Fig. 2) In specimen sixteen the distended saccular wall also lies in contact with a distended cochlear duct In two ears (Figs 38 and 45) the enlarged saccule extends into the nonampulated end of the lateral semicircular canal a condition previously described by Altmann (1943) Lindsay (1944) Day (1949) Altmann (1965) and Lindsay (1967) (Fig 3)

In most specimens the reinforced area of the saccular wall retains its normal position suggesting that it is more resistant to distortion by the effects of the endolymphatic hydrops (Fig. 4)

Membrane collapse

It is not always possible to determine whether collapse of labyrinthine membranes represents postmortem or antemortem changes as pointed out by Schuknecht (1968*c*)

Membranes which are distended and thus possibly weakened may be more susceptible to preparation artifacts A good example of antemortem collapse is seen in ear four which has a collapsed but previously distended cochlear duct In the collapsed lumen there is acidophilic fluid and precipitate (Figs 5 and 6) Ears two and four (Figs 28 and 30) show partially collapsed saccular walls and ear nine (Fig. 35) shows a previously distended cochlear duct which appears to have been compressed and collapsed against the foot



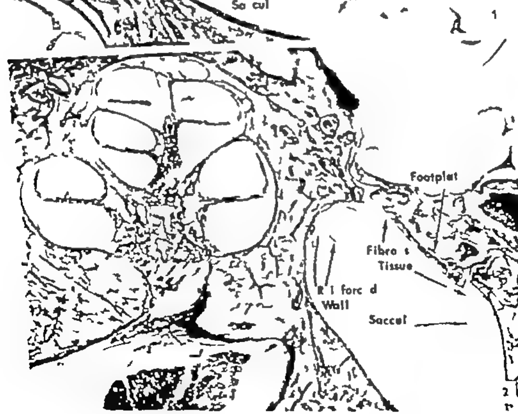


Fig. 1 (Case ... Distended ductus reuniens occupying much of the vestibule. There is an endolymph-to-endolymph fistula between the saccule and the distended ductus reuniens.

Fig. 2 (Case ... W. not included in the volumetric study) Distended saccule with fibrous tissue proliferation under the footplate of the stapes and lateral wall of the vestibule.

plate and lateral wall of the vestibule by the distended saccule (Fig 7)

Membrane ruptures

The interpretation of the breaks in the continuity of membranes must be based on associated morphological changes as well as on the quality of the histological preparation For example a rupture in the membranous labyrinth adjacent to a small fissure in the bony labyrinth would be suggestive of preparation artifcat Also breaks in the membranes of an opposite ear (without Meniere s disease) would suggest artifact The difficulties in making these judgements have been discussed by Lindsay (1960) Schuknecht (1962) and Altmann (1965) However taking these factors into account it appears that there are antemortem ruptures of Reissner s membrane in eight ears (Figs 31 33 34 36 37 39 40 and 45) and in the saccule in eleven ears (Figs 31 32 34 35 37 38 39 40 43 44 and 45) Ear five (Fig 31) shows three ruptures in the cochlear duct and one in the saccule Ear eleven (Fig. 37) shows one in Reissner s membrane and two in the saccule and ears eight thirteen fourteen and nineteen (Figs 34 39 40 and 45) show one rupture in Reissner s membrane and one in the saccule

Kristensen (1961) and Blättler et al (1973) described ears in which Reissner s membrane was herniated through the helicotrema and extended into the second turn without ruptures These extensive dilatations without ruptures suggest that should there be an increase in endolymphatic pressure it is a slow and insidious process

In six of eight ears with rupture of Reissner's membrane the ruptures occurred in the area of maximum dilatation (Figs 33 34 37 39 40 and 45) and in only two did it occur elswhere (Figs 31 and 36) (see Fig. 8)

Study of the saccules show that ruptures are present in each of two ears with severe distention (Figs 38 and 45) eight of ten with moderate distention (Figs 32 34 35 37 39 40 43 and 44) and one of five with mild distention (Fig 31) Altmann & Kornfeld (1965) are of the opinion that it would be improbable that more than one rupture would occur in the same structure This obviously would pertain if healing of the breaks did not occur This point will be further discussed in the section describing ruptures in the superior labyrinth

Ear five (Fig. 29) which shows a large rupture of Reissner's membrane in the basal turn also shows atrophy and encapsulation of the tectorial membrane in the same region (Figs 8 and 31) This was the only ear in which there was a spatial correlation of a break in Reissner s membrane with another structure of the cochlear duct

Because all ears presented relatively uniform patterns of threshold loss on audiometric testing it is obvious that the ruptures of Reissner s membrane did not create a selective loss of hearing in the auditory spectrum

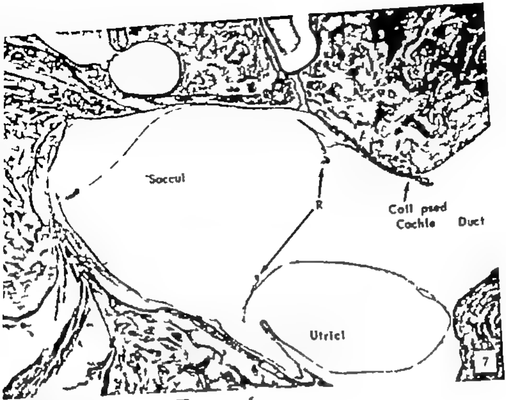
2. The superior labyrinth (Utricle and semicircular canals)

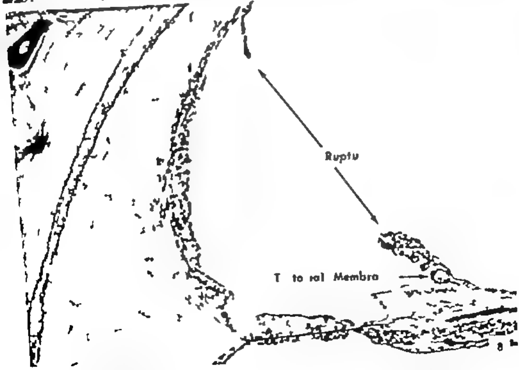
Membrane dilatation

The walls of the superior labyrinth are thicker and probably more resistant to distortion In none of these specimens was the utricular dilatation as striking as that described by Lindsay (1942)

Membrane collapse

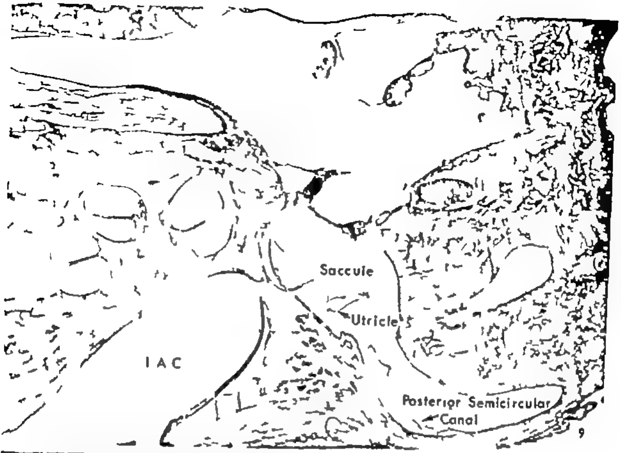
Severe collapse is rarely found in the superior labyrinth and in only two ears eleven and six (Figs 37 and 32) is there collapse in this region In ear eleven (Fig 37) the collapse is thought to be antemortem because (1) the utriculo-endolymphatic valve is compressed by an enlarged saccule (Fig 9) whereas in all other specimens the utriculo-endolymphatic valve is normal or open (Fig 10) (2) there is an eosinophilic pink staining fluid filling the superior labyrinth (Fig. 9) probably an indica





F (Case 9) Severe dilatation of the saccule. The herniated cochlear duct is compressed against the lateral all of the vestibule by the distended saccule. Note the utriculo-endolymphatic valve is open.

Fig. 8 (Case 5) Rupture of Reissner membrane and encapsulation of the tectoral membrane.



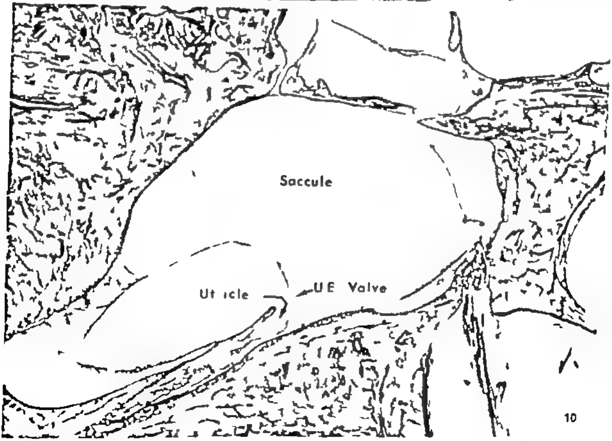


Fig 9 (Case 11) Severe dilatation of the saccule *compressing the utriculo-endolymphatic valve* There is an acidophilic staining fluid in the utricle and semicircular canals.

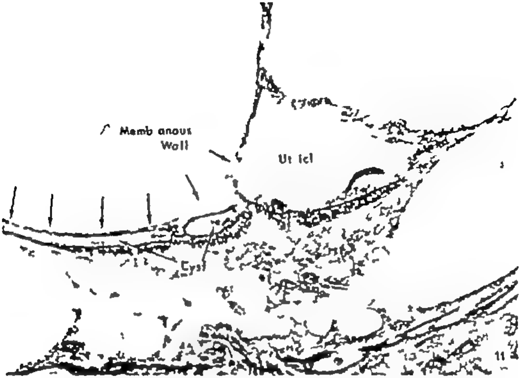
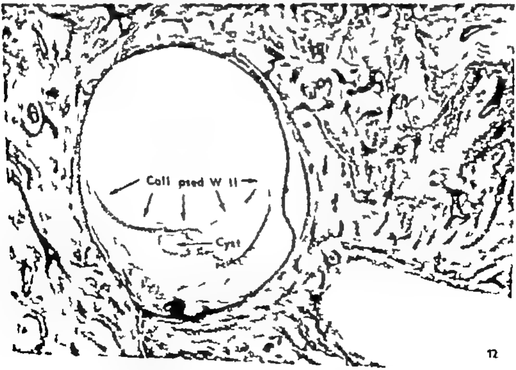
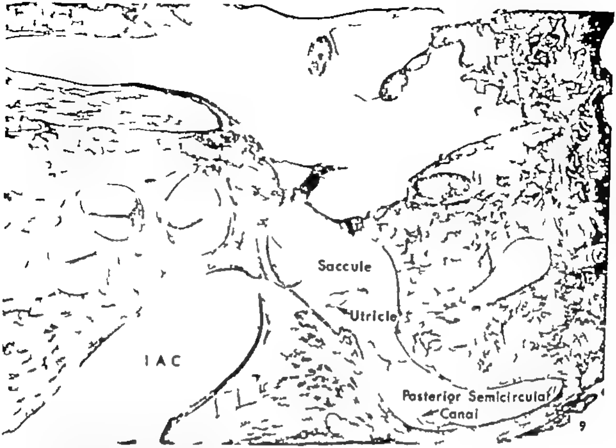
Fig 10 (Case 6) The utriculo-endolymphatic valve is open.





F 11 (Case 11) Collapsed utricular all showing stic formations and areas of disruption of the sensory epithelium of the utricular macula

Fig 12 (Case 6) Collapsed wall of the ampulla of the superior semicircular canal Cystic degeneration of the subepithelial tissue of the crista.



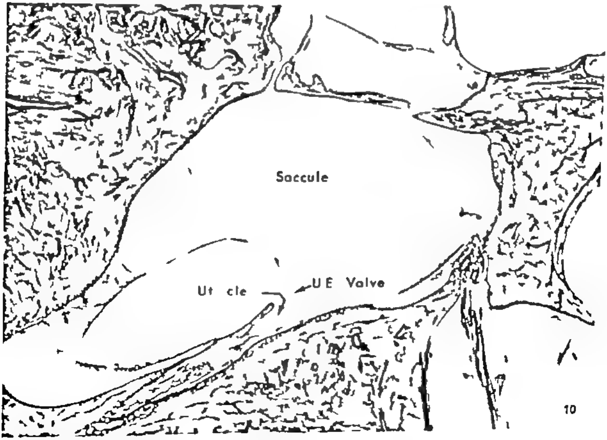


Fig 9 (Case 11) *Severe dilatation of the saccule compressing the utriculo-endolymphatic valve There is an acidophilic staining fluid in the utricle and semicircular canals.*

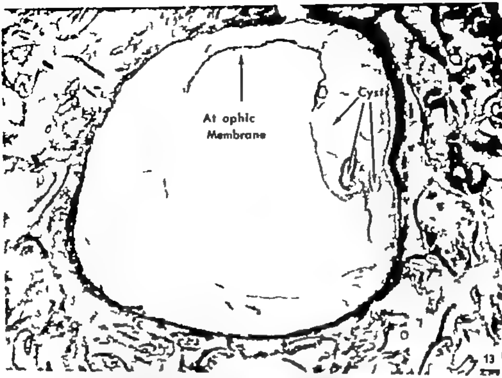
F g 10 (Case 8) *The utriculo-endolymphatic valve s open.*



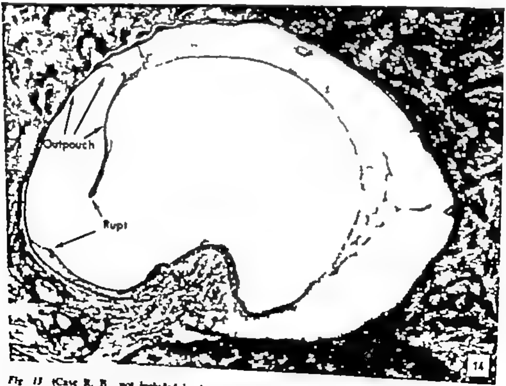


Fig 13 (Case R. B not included in the volumetric study) Cystic degeneration of the posterior canal. There is acidophilic staining fluid filling the cysts. There is an area of degeneration of the ampullary wall.

Fig 14 (Case 7)- Rupture of the ampulla of the posterior semicircular canal. This is the most common site for ampullary ruptures. The fistula appears to lead to pouch ...th intact walls.

tion of interference with fluid resorption and (3) the utricular macula shows epithelial adhesions to the collapsed utricular wall cystic formations and disruption of the epithelium (Fig 11) In case six (Fig. 12) there is not only displacement of the ampullary wall of the superior canal but also cystic degeneration of the subepithelial tissue with an acidophilic staining fluid filling the cyst These changes could be secondary to the membranous collapse although similar changes have been found in the posterior canal ampulla of another specimen which did not show a collapse of the ampullary wall (Fig. 13) Degeneration of the sensory epithelium of the vestibular system is rare in Meniere s disease for this is the first report of this pathological change

Membrane ruptures

Nine of the utricules show discontinuity of the membranous walls (Figs 29 31 33 35 36 38 40 43 and 45) five in the superior half and seven in the inferior half of the utricle

There are fifteen ruptures in the ampullae three in the lateral canal (Figs 33 40 and 45) three in the superior canal (Figs 40 43 and 45) and nine in the posterior canal (Figs 33 37 40 43 45) In two ears the ampullae show two outpouchings (Figs 37 and 45) and in one ear there are three (Fig 43) Outpouchings in the semicircular canal ampullae are most often found surrounding the cristae and area semilunata as shown in Fig 14

The defects in the walls of the superior halves of the utricles and the semicircular canal ampullae correspond to those described by Schuknecht (1968*a* 1968*c*) (Figs 15 and 16) The ruptures in the inferior part of the utricle appear similar to those seen in Reissner s membrane and the saccule with actual openings into the endolymphatic space. Five of these latter ruptures were found very close to the utriculo-endolymphatic valve area (Figs 35 36 38 40 and 45)

Only one rupture was found in the semicircular canals (Fig 43) and this is located in the non ampullated end of the posterior semicircular canal near the common crus The outpouching type of rupture is found characteristically in the ampullae and superior halves of the utricles Schuknecht s interpretation of the outpouchings as representing healed ruptures seems to be supported by recent experimental observations of Kimura & Schuknecht (1975) who have demonstrated the remarkable propensity of the membranous labyrinth to heal

III Volumetric Study

MATERIAL AND METHOD

Material

Histological preservation and preparation are suitable to permit volumetric studies of the cochlear ducts of seventeen specimens and the ampullae of the posterior and superior semicircular canals in six cases in which the opposite normal sides are available

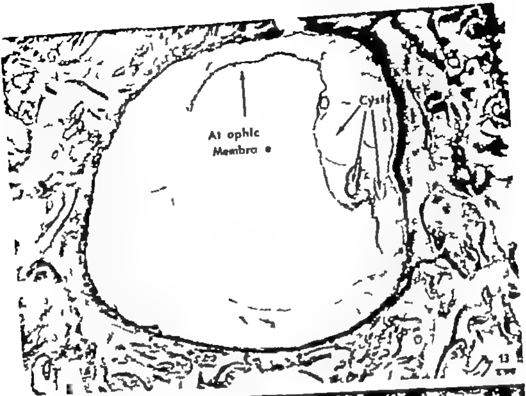
The ampullae of the lateral canals and the utricles could not be studied because of the plane of sectioning.

Twenty temporal bones from ten individuals without clinical or histopathological evidence of pathology are studied and serve as a control

Method

The word volume" has been chosen to express an estimate of the volume derived from the cross sectional areas of the cochlear spaces at different levels along its length

To estimate the increase in area of the cochlear duct (*B* in Fig. 20) and corresponding decrease in area of the scala vestibuli (*C–B* in Fig. 20) six points have been selected



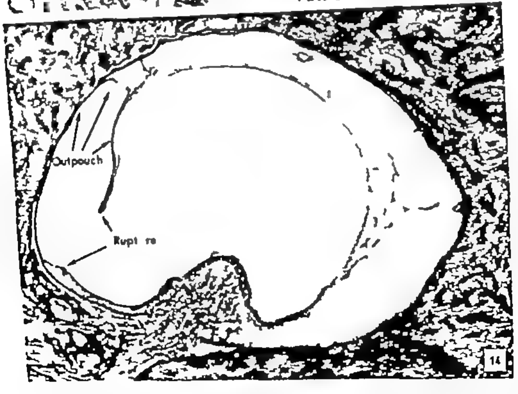


Fig. 13 (Case R. B. not included in the volumetric study). Cystic degeneration of the posterior canal. There is acidophilic staining fluid filling the cysts. There is an area of degeneration of the ampullary wall.

Fig. 14 (Case 7) Rupture of the ampulla of the posteri[or] semicircular canal. This is the most common site f[or] ampullary ruptures. The fistula appears to lead to a pou[ch] with intact walls.

tion of interference with fluid resorption and (3) the utricular macula shows epithelial adhesions to the collapsed utricular wall cystic formations and disruption of the epi thelium (Fig 11) In case six (Fig 12) there is not only displacement of the ampullary wall of the superior canal but also cystic degeneration of the subepithelial tissue with an acidophilic staining fluid filling the cyst These changes could be secondary to the membranous collapse although similar changes have been found in the posterior canal ampulla of another specimen which did not show a collapse of the ampullary wall (Fig. 13) Degeneration of the sensory epithelium of the vestibular system is rare in Meniere s disease for this is the first report of this pathological change

Membrane ruptures

Nine of the utricules show discontinuity of the membranous walls (Figs 29 31 33 35 36 38 40 43 and 45) five in the superior half and seven in the inferior half of the utricle

There are fifteen ruptures in the ampullae three in the lateral canal (Figs 33 40 and 45) three in the superior canal (Figs. 40 43 and 45) and nine in the posterior canal (Figs 33 37 40 43 45) In two ears the ampullae show two outpouchings (Figs 37 and 45) and in one ear there are three (Fig 43) Outpouchings in the semicircular canal ampullae are most often found surrounding the cristae and area semilunata as shown in Fig. 14

The defects in the walls of the superior halves of the utricles and the semicircular canal ampullae correspond to those described by Schuknecht (1968*a* 1968*c*) (Figs 15 and 16) The ruptures in the inferior part of the utricle appear similar to those seen in Reissner s membrane and the saccule with actual openings into the endolymphatic space. Five of these latter ruptures were found very close to the utriculo-endolymphatic valve area (Figs 35 36 38 40 and 45)

Only one rupture was found in the semicircular canals (Fig. 43) and this is located in the non ampullated end of the posterior semi circular canal near the common crus The outpouching type of rupture is found characteristically in the ampullae and superior halves of the utricles Schuknecht s interpretation of the outpouchings as representing healed ruptures seems to be supported by recent experimental observations of Kimura & Schuknecht (1975) who have demonstrated the remarkable propensity of the membranous labyrinth to heal

* Presbycusis.

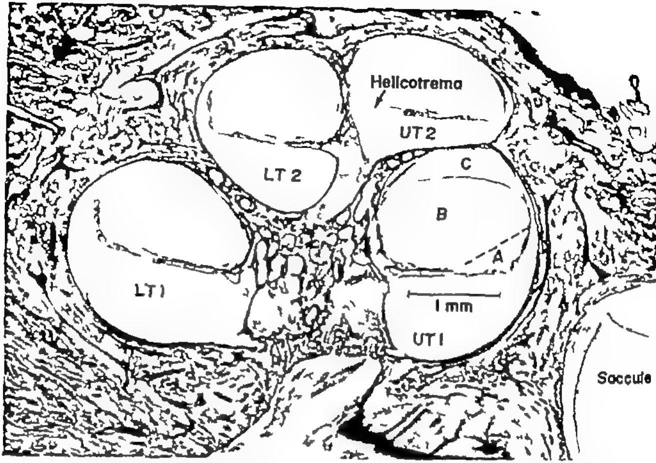

Fig 19 (Case 9) Midmodiolar section. The dotted line represents Reissner's membrane assuming its normal position. This case and number six are the right and left sides of the same patient. Both sides present a small (30 mm.) cochlea. Lower turn one (LT_1) upper turn one (UT_1) Lower turn two (LT_2) upper turn two (UT_2). Assumed normal cochlear duct (*A*) increased volume (*B*) and scala vestibuli (*C*)

along the length of the cochlea A midmodiolar section has been chosen since it is perpendicular to the cochlear partition at five different levels corresponding to the *12 19 25 29* and 31 mm cochlear regions The sixth level has been arbitrarily selected in the 2 to 3 mm region

For each section a drawing is made by projecting the slides with a Bausch and Lomb slide projector (47×) The points at which Reissner's membrane is attached to the limbus spiralis and basilar crest (spiral ligament) are determined by histological appearance or arbitrary decision These points are shown as (*a*) and (*a'*) in Fig. 20 From (*a*) to (*a'*) the following lengths were measured (1) the length of the distended Reissner's membrane (2) the length of the walls limiting the scala vestibuli (3) the length of the walls limiting the scala media

In order to measure the length the outlines of each of the described spaces are traced with a graphical input device (SAC graph/pen) attached to a PDP 8/E computer The computer determined the required lengths by sampling the contours at an interval which would correspond to 18 micrometer on the slide A special computation procedure is used to estimate the areas The fully distended membrane was assumed to have formed an arc convex into the scala vestibuli and the normal position of Reissner's membrane is taken to be a straight line between (*a*) and (*a'*) in Fig. 20 The computer program then computed an equivalent area for each of the lengths (1) (2) and (3) above by assuming that each

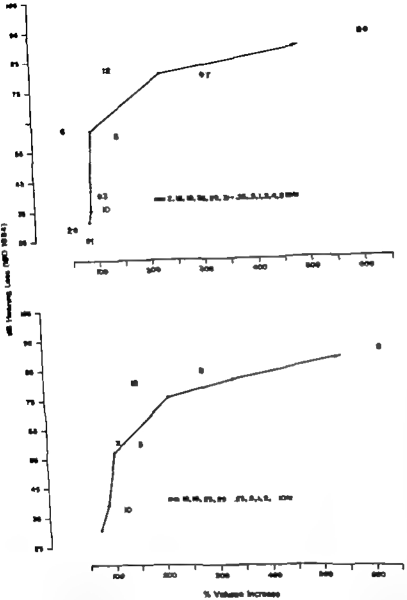

Fig 22 Volumetric study Average percentage volume increase versus average hearing loss for cases one through twelve. The number on the data points indicat the case number (*Top*) All measurements and cor responding frequencies are included (*Bottom*) Measurements on mm 2 and 31 and their corresponding audiometric values have been excluded.

13 Fig. 3) or there is no response to all the tested frequencies (case 14 Fig. 40)

In the twelve ears that were studied, the data permitted a correlation between the hearing loss and the magnitude of increase in endolymph of the cochlear duct. The average increase is computed for two groups, one with hearing loss (ISO 1964) greater than seventy decibels (cases 7 8 9 11 12, Table I) and the other with hearing loss less than seventy decibels (cases 1 2, 3 4 5 6, 10) The data shows a greater increase in endolymph in the group of ears with the greater hearing loss (Fig. 1). The curve for the cases with a hearing loss less than 70 db has a higher percentage of volume increase in the apical turn (mm 25 to 31) of the cochlear duct than in the middle and basal turns. The curve in the advance cases has a greater percentage of volume increase in the middle and basal

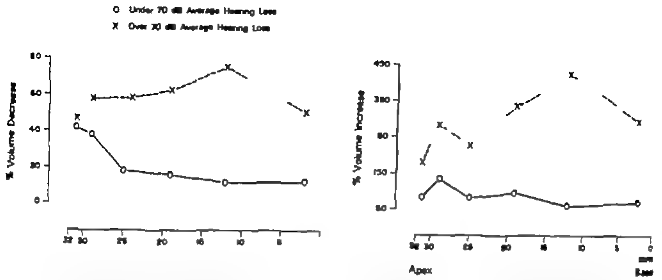

Fig 21 (*Right*) Average ratio of increase in volume of endolymph to the normal volume (*B/A* Fig 20) — group of individuals with a hearing loss less than 70 db group of individuals with a hearing loss greater than 70 db (*Left*) Average ratio of increase of endolymph to remaining perilymph in the scala vestibuli (*B/C* Fig 20) — group of individuals with hearing loss less than 70 db group of individuals with hearing loss greater than 70 db (see text, "Volumetric Study")

boundary formed an arc passing through (*a*) and (*a'*)

The percentage increase in area is obtained by dividing the distended' measurement (*B*) by the normal measurement (*A*) thus % increase = *B/A* (Fig 20) The ratio of the areas of increased endolymph to remaining perilymph is also determined (*B/C* Fig 20) These measurements made at six points (2 12 19 25 29 and 31 mm) are adjusted to fit a uniform 32 mm cochlear model in the cochleae which measure longer or shorter than 32 mm (see Fig 19)

The areas of the superior and posterior semicircular canal ampullae are measured in sections cut at right angles to the middle region of the cristae in this case the cord (*a–a*) corresponds to the edges of the cristae

Studies have been done on the cross section of the cochlear duct scala vestibuli and scala tympani in the normal human (Weber 1949) and guinea pig (Fernandez, 1952) Kimura, in 1967 also studied the percentage of volume increase in guinea pigs with induced hydrops

Because this method is based on the assumption that the limiting walls of the inner ear spaces form an arc the areas thus obtained are larger than the actual ones Therefore the available data from previous studies cannot be compared to the present study in absolute values For this reason we shall refer to relative values

I The inferior labyrinth

With the previously described method the cross sectional areas are determined for the cochlear duct scala vestibuli and distended cochlear duct Obviously the area of the scala vestibuli decreased as the area of the cochlear duct increased Although the precise physiological functions of the perilymph are unknown it is possible that a decrease in perilymph volume as well as an increase in endolymph may be of pathological significance

A possible relationship of the two fluids has been suggested by previous authors (Altmann & Waltner 1950 Tonndorf 1962 Ilberg & Vosteen 1969)

Cases excluded from this study are those in which the audiometries are not available or the volumetric study could not be performed Cases thirteen and fourteen have also been excluded because there is audiological evidence of presbycusis in the opposite side (case

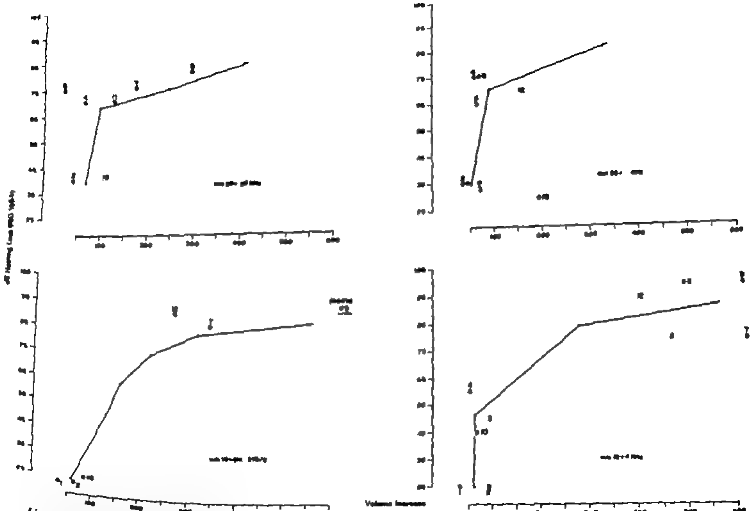

Fig 24 Volumetric study Volume increase versus hearing loss, direct correlation. Cases one through twelve —cochlear measurements and hearing evaluation for mm 29 and 0.25 KHz, mm 25 and 0.5 KHz, mm 19 and average hearing loss for 1 and 2 KHz, and mm 12 and 4 KHz.

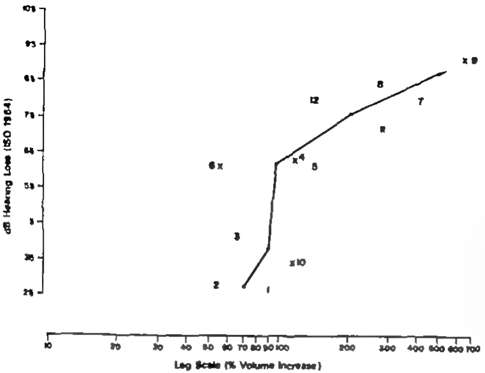

Fig 23 Volumetric study Average percentage volume increase versus average hearing loss for cases one through twelve Measurements on mm 2 and 31 have been excluded Note logarithmic horizontal scale.

turns of the cochlear partition (mm 2 to 20 Fig 21)

A clear correlation to the audiometric pattern could not be found by grouping the cases according to their flat ascending or descending patterns (Table I 20 db criterion)

In order to evaluate the relationship of volume increase versus hearing loss for each case the mean thresholds for the frequencies 0 25 0 5 1 2 4 and 8 KHz, were plotted against the corresponding cochlear measurements (Fig. 22) The data demonstrates a direct relationship between them. Because the range of measured areas for the normal cochelar duct in the extreme regions are very broad (0 48 mm² and 0 40 mm² respectively Fig. 20) the same correlation has been made excluding the measurements for the hook region (mm 2–3) and the third turn (mm 31) Their corresponding audiometric values were also excluded Under these circumstances the curve becomes smoother (Fig 22) Since the increase in intensity in the clinical evaluation of the hearing loss is exponential (db) the values of the volume increase have been plotted on a logarithmic scale in fig 23 The curve thus obtained has two sections the first having a very steep slope up to 70 db (over 100 db/Dec) second with a slower rise (40 db/Dec) for hearing losses over 70 db This correlation has also been found for each location of measurement (UT2 LT2, UT1 LT1) and their corresponding representation in the audiogram (Fig 24)

The wide range in the measurements could be explained by the inevitable differences in the plane of sectioning which are more pronounced at each end of the cochlea (Fig.

Table II *Volumetric study posterior and superior ampullae*

	Average (mm³)	Range
Normal (N 10)		
Superior amp. R.	1 857	2.825–1.387
Superior amp. L.	1 720	2 108–1 270
Posterior amp. R.	1 813	2.142–1 304
Posterior amp. L.	1 933	2.343–1 604
All ampullae	1 830

* Small ampulla. Next value between brackets.

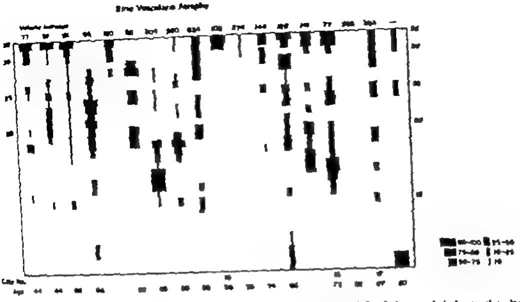

Fig. 26 Evaluation of the stria vascularis. The black columns represent the percentage of strial atrophy. The figures on the left of the graph indicate the site along the cochlea in millimeters.

The average area for the superior canal ampullae is 1.826 mm² (range 2.693–0.934) in the normal side and 1.682 mm² (range 2.157–0.887) in the Meniere's side. The average area for the posterior canal ampullae is 1.904 mm² (range 2.546–1.384) in the normal side and 2.033 mm² (range 2.734–1.624) in the Meniere's side. The difference between Meniere's side and the opposite normal side is 0.144 mm² (larger in Meniere's side) for the superior canal and 0.129 mm² (larger in the normal side) for the posterior canal.

Differences in the areas of section between the normal and pathological ears in unilateral cases of Meniere's disease are not significant (Table II).

IV Cochlear Sensory and Neural Structures

1 THE ORGAN OF CORTI

In all the ears, the hair cell population appeared to be normal for age. Losses at the basal ends of the cochleae are presumed to be caused by aging and are found in ears without Meniere's disease. In four cases with unilateral Meniere's disease the hair cell populations appeared to be identical to that of the opposite ears. In case four (*fig. 30*) the opposite ear shows a severe *hair cell loss* of unknown cause in the first 5 mm of the cochlea. In case ten (Fig. 36) the opposite ear shows a hair cell loss in the 7 to 13 mm region and a hearing loss for 4 KHz and 8 KHz which is compatible with *unilateral* acoustic trauma. These observations relate only to the presence or absence of sensory cells, which does not necessarily imply that the present cells are functional.

2. THE SPIRAL GANGLION

1 *Ganglion cell loss due to aging*

In the interpretation of the findings in the spiral ganglion cell population the age of the patient has to be taken into consideration. For it has been established that there is a ganglion cell loss of varying degree in the basal turn of

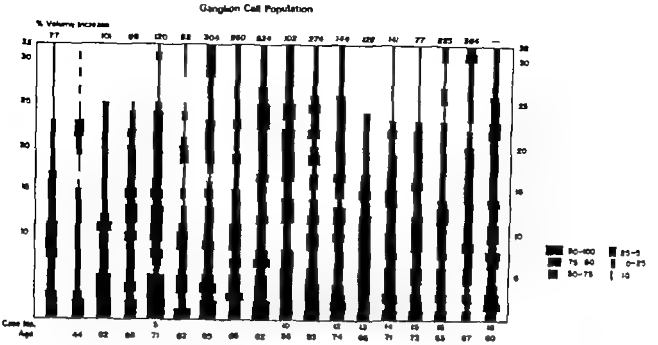

Fig 25 Evaluation of the spiral ganglion The black columns represent the percentage of ganglion cell loss The figures one through thirty-two on the left of the graph indicate the site along the cochlea in millimeters.

20) The presence of the helicotrema in the mm 31 complicates the determination of the boundaries of the scala vestibuli

Since the angle of section is the same for all the measurements made at the same location small changes in this angle should not have a significant effect on the percentage values

2. The superior labyrinth

Measurements of corresponding ampullae of right and left ears were made on twenty temporal bones from ten individuals with no clinical or pathological evidence of otological disease (Table II) *According to the previously* described method the average area for the superior and posterior canal ampullae is 1 830 mm^2 (range 2 825–1 270) The average area for the superior ampullae is 1 788 mm^2 (range 2 825–1 270) and for the posterior ampullae 1 873 mm^2 (range 2 343–1 304) The difference between the average superior and posterior ampullae is 0 085 mm^2 The difference between right and left is 0 137 mm^2 *for the superior ampullae and 0 209 mm²* for the posterior ampullae

In the six individuals with unilateral Meniere s disease in which the opposite normal side was available for study the average area of the superior and posterior ampullae in the normal side is 1 865 mm^2 (*range* 2.693–0 934) and the average area in Meniere s is 1 857 mm^2 (range 2 734–0 887)

Table III *Loss of cochlear neurons*

	Estimated % ganglion cell loss		
	Age		
Location	Under 65	65 and over	Difference
0 to 10 mm	51%	66%	15%
11 to 25 mm	37%	43%	6%
26 to 32 mm	16%	18%	2%

Table IV *Loss of cochlear neurons*

	Estimated % ganglion cell loss		
	Vol. incr

11 to 25 mm	41%	39%	[illegible]
26 to 32 mm	13%	3%	10%

Fig 27

CASE No 1

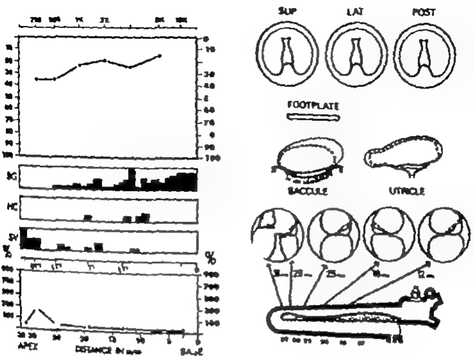

Fig 28

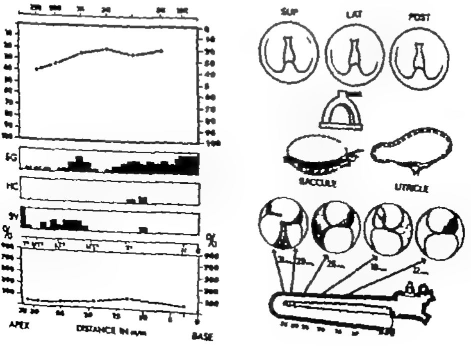
CASE No 2



the cochlea due to aging (Otte 1968) To evaluate the role of aging as a cause for loss of ganglion cell population in these specimens two groups were compared those in the age group 0–64 years and those over 64 years (Table III Fig. 25)

The average age in the first group is 54 years (Cases 1 2 3 6 9 10 11 16 Table I) The average age for the group of individuals over 65 years is 70 years (Cases 4 5 7 8 12 13 14 15 17 Table I) The average volume increase is 189% for the "younger" age group and 181% for the "older" age group

The difference in the ganglion cell population of these groups is minimal in the 25 to 32 mm cochlear region (Table III) In the 10 to 25 mm region there is a small difference and it becomes significantly larger for the "older group in the first 10 mm of the cochlea. This finding is consistent with previous studies (Otte 1968)

2 Ganglion cell loss due to hydrops

A correlative study has also been made grouping these cases according to the percentage of volume increase The first group (N 9) including cases with a percentage of volume increase less than 130% (average 90%) and the second (N-8) including cases with a percentage of volume increase over 130% (average 292%) The average age for the first group is 66 years and the average age for the second group is 60 years A correlation of ganglion cell loss to the volume increase was found only for the last 7 mm of the cochlea (Table IV)

3 THE STRIA VASCULARIS

There is atrophy of the stria vascularis in all but one of the specimens (case 16 Fig. 42) (see Fig. 26)

The strial atrophy is more severe in the apical two-thirds of the cochleae in all cases. There is a striking similarity between the pattern of the atrophy in these specimens and that found in presbycusis (Schuknecht & Ishii 1966 Belal 1974 Schuknecht et al 1974) (see Fig. 26)

V Synopsis

The following is a display of the nineteen (Figs 27 to 45) cases studied Each figure represents a single case Some clinical data for these cases are available in Table I The pathological findings and volumetric study have been represented in two diagrams as follows

1 Left diagram

The upper graph shows pure tone thresholds with the stimated frequency distribution on the anatomical frequency scale that is in accordance with their spatial location along the cochlear duct (Schuknecht 1968*b*)

The second graph (S G) presents the spiral ganglion evaluation given in percentages of ganglion cell loss (black)

The third graph (H C) presents the hair cell population given in percentages of hair cell loss (black)

The fourth graph (S V) presents the evaluation of the stria vascularis given in percentage of degeneration (black)

The lower graph presents the percentage of volume increase in endolymph (B/A Figs 19 20) determined in six regions of the cochlea corresponding to H=hook region (2 to 3 mm region) LT_1=lower half of the first turn (12 mm region) UT_1=upper half of the first turn

The ordinate shows the percentage increase in area of the cochlear duct in these regions (see text Volumetric Study) The lower abscissa indicates distance along the cochlear duct

2. Right diagram

This diagram is a schematic representation of the studied inner ear membranes as seen under light microscopy The black arrows labeled with an "R" appearing in some plates point to the approximate site of the ruptures The dotted lines for the utricle and saccule represents an arbitrary normal volume

Summary and Conclusions

This study is based on a detailed examination of the histopathological findings in twenty five temporal bones from twenty individuals with Meniere s disease

Interpretation of the findings in human temporal bone pathology is complicated by numerous factors e g postmortem autolysis preparation artifacts coincident pathology long intervals between clinical evaluation and death of the patient etc For this reason only consistent findings and definite correlations will be considered

SUMMARY

Histopathologic findings in the labyrinthine membranes

1 *The inferior labyrinth*

Dilatation of the inferior labyrinth is present in varying degrees in all the specimens Hernia-

tion of Reissner's membrane through the helicotrema is found in two specimens (Figs 33 34)

In ten ears the lateral wall of the saccule or the distended ductus reuniens are in contact with the stapes footplate Four of these specimens show a fibrous tissue formation between the membranous wall and the endosteum of the footplate (Fig. 1 2)

The reinforced area of the saccular wall retains its normal position regardless of the degree of distention of the saccule

Definite antemortem collapse of the membranous walls of the cochlear duct are present in two specimens (Figs 5 6 7)

In six out of eight ears with rupture of Reissner's membrane the ruptures are located in the areas of maximum distention Similarly ruptures of the saccular walls are found more frequently in cases of severe or moderate distention than in cases of mild distention.

There is no spatial correlation between the ruptures of Reissner's membrane and the hearing loss Only one ear (Fig. 8) presents pathology at the site of the rupture

2. *The superior labyrinth*

Dilatation of the utricle is mild or absent. Two ears show evidence of antemortem collapse (Figs. 11 and 12)

Two different types of rupture are found in the superior labyrinth The first type (type I) shows a direct communication between the endolymphatic and perilymphatic spaces This type of rupture is only present in the inferior halves of the utricle and the inferior labyrinth

The second type (type II) is characterized by a gap in the normal continuity of the membranous wall sealed by a unicellular replacement membrane Type II ruptures are only found in the semicircular canals and the superior halves of the utricles (Figs. 14 15 16) This type of rupture is most commonly found in the posterior canal ampullae Multiple ruptures of the type II are not infrequent (Fig. 17) and can also be found associated to type I ruptures Some type II ruptures are surrounded by areas of atrophy of the wall (Fig. 18)

The utriculo-endolymphatic valve appears normal or open in all but one specimen (figs 7 10)

3 *Volumetric study*

As previously stated the word "volume" is used to express an estimate of the volume derived from the cross sectional areas of the cochlear spaces at different points along its length

In the cochlea, the average increase in volume of endolymph is computed for two groups one with a hearing loss greater than seventy decibels (db ISO 1964) (N 5) and the other with hearing loss less than seventy decibels (N 7) Comparing the two groups, the volume increase is greater in the group of ears with a hearing loss over 70 db than in the group of ears with a hearing loss under 70 db

The group of ears with a hearing loss less than seventy decibels has a greater volume increase in the apical turn than in the middle and basal turns The group of ears with a hearing loss over seventy decibels has a greater volume increase in the middle and basal turns than in the apical turn (Fig. 21)

The curve obtained by plotting the average percentage of volume increase against the average threshold elevation for the frequencies 0.25 0.5 1 2, 4 and 8 KHz (Figs 22, 23) shows a definite correlation. This correlation can be seen clearly in bilateral cases where causes of error such as hearing loss due to aging, time lapse following death or errors due to calibration of the audiometers, are minimized (Figs. 22, 23 24)

In the superior labyrinth the measurements included six cases with unilateral Meniere's disease in which the opposite normal sides are available and suitable for study The measurement indicates that the differences between both sides are not significant (Table II)

4 *Cochlear sensory and neural structures*

The hair cell population is normal for age in all specimens This observation relates only to the presence or absence of sensory cells and does not imply that the present cells are functional

There is a ganglion cell loss due to aging The loss is more pronounced in the first 10 mm of the cochlea. This finding is in agreement with previous studies (Otte 1968)

There is a greater percentage of ganglion cell loss in the last 7 mm of the cochlea in the cases of Meniere s disease where the volume increase is over 130% (Table II Fig 25)

There is atrophy of the stria vascularis of varying degrees in all but one of the specimens (Case 16 Fig. 26) In all cases the strial atrophy is more severe in the apical two thirds of the cochlea. There is a striking similarity between the pattern of the atrophy in these specimens and that found in presbycusis (Schuknecht & Ishii 1966 Belal 1974 Schuknecht et al 1974) (Fig 26)

For this reason no attempt has been made to correlate the amount of hydrops with the strial atrophy

CONCLUSIONS

In the interpretation of the histopathological findings in this study we must bear in mind that the morphological changes found at the time of death represent only a stage in the evolution of Meniere s disease To draw any final conclusions with regard to the pathogenesis of Meniere s disease on the basis of these findings would be speculative

However the data obtained from this study suggest that

(1) *There is no clear correlation between* the sensorineural hearing loss and the histopathological findings in the sensory and neural structures

(2) The increase in volume of endolymph is directly related to the hearing loss

In the cases with an average hearing loss less than seventy decibels the temporal bones show a small percentage of increase in endolymph per decibel of hearing loss and the volume increase is more severe in the apical turn than in the middle and basal turns

In the cases with an average hearing loss over seventy decibels the temporal bones show a high percentage of increase in endolymph per decibel of hearing loss and the increase is greater in the middle and basal turns than in the apical turn

(3) There are two different types of ruptures of the membranous walls The "type I" ruptures are of doubtful significance for the following reasons (*a*) They are frequently found in the walls of the inferior labyrinth which are thinner and more distended than the walls of the superior labyrinth and therefore possibly more susceptible to preparation artifact (*b*) They do not show consistent pathological changes at the edges (*c*) Only one temporal bone shows associated pathology in the sensory structures at the site of the rupture

The "type II" ruptures are believed to be antemortem for the following reasons (*a*) They show evidence of a reparative process at the edges and a thin replacement membrane seals the discontinuity of the normal wall (*b*) In some instances the edges show evidence of atrophy

The cause of this rupture cannot be explained solely on the basis of an increase in endolymphatic pressure

It has not been established that the increase in endolymphatic volume reflects an increase in endolymphatic pressure The fact that two or more "type II" ruptures are frequently found within the same superior labyrinth would suggest that factors other than an increase in endolymphatic pressure alone are involved in the pathogenesis of this rupture Localized areas of atrophy of the labyrinthine walls could be a factor in causing these ruptures

The protein manifestations of vestibular dysfunction in Meniere s disease may be ex

plained by the varied histopathological findings. Alterations of the physical properties of the labyrinthine membranes e.g. distention, collapse and rupture and possible biochemical changes in the labyrinthine fluids could account for the peripheral vestibular dysfunction It is not possible at this time to assign a particular vestibular symptom to a specific morphological change

Acknowledgements

The author is greatly indebted to Dr Harold F Schuknecht for his encouragement and direction during the study and preparation of this manuscript. Acknowledgement is also due Mr Terrance Bourk for his technical advice in the volumetric study and computer programing and to Mr Robert S Kimura for his advice during this study I also wish to thank Mrs Diane Jones for the preparation of the histopathological material and Ms Elaine Joseph for her help in the preparation of this manuscript.

URBAN TRAFFIC NOISE
AUDITORY AND EXTRA AUDITORY EFFECTS

Introduction bibliographical survey research aims and technical notes

G Rossi

From the Department of Audiology University of Turin, Turin, Italy

INTRODUCTION

Noise is responsible for four closely linked effects in man These relate to a) hearing b) vegetative functions (cardiocirculatory system, sleep, endocrine performance and the gastrointestinal apparatus) c) interpersonal relations (state of attention and wakefulness, speech and behaviour) d) overall repercussions on physical and mental activity determined by the degree and type of "disturbance and annoyance" caused by the noise in question. There are, of course, no hard and fast boundaries between these effects. Prolonged interference with sleep, for example, is not without its effect on interpersonal relations, to the extent that the "disturbance and annoyance" brought about by ambient noise tends to be exaggerated by a given subject.

Over and above a general statement of this kind, which seeks to stress the limits of this classification, while acknowledging its usefulness, at any rate for illustrative purposes, attention must be given to the relevant literature.

The "Effects of noise on man" have been fully examined over the last twenty years, as a glance at the extensive bibliography compiled by Kryter (1970) in his book on this subject will readily show

Yet the attentive reader will notice that most attention has been directed to the effects of industrial noise. This approach, of course, is fully justified by the noise levels to be found in work environments. In addition, it enables weight to be given to the fact that the contact between men and machines is "enforced" rather than "voluntary"

Voluntary associations between human beings and sources of noise may be discerned solely in the field of individual and communal recreation. Leaving aside situations of this type, the links between man and noise forming an integral part of modern life are not so much the result of "enforcement" as of "unavoidable necessity

Considerations of this kind are of particular importance when dealing with the relation between man and his environment outside working ambients, since here traffic noise is the prime factor In a word, whether we work in quiet or noisy surroundings, we are necessarily subjected to a noisy background.

Two questions may be asked Is this noisy background harmful to health in itself? To what extent are its effects additional to those produced by noise at work? No firm answer can as yet be given. The hesitant opinions expressed in the literature, however show that the matter is one that deserves attention.

BIBLIOGRAPHICAL SURVEY

Effects on hearing

Very few data exist. Lang & Jensen (1967) investigated a possibility of increases in the temporary threshold shift (TTS) in subjects who had driven for 12 hr non-stop TTS changes are dependent on personal factors and appear to be closely linked to the length of exposure to

to have been neglected in the literature. The same appears to be true with respect to changes in cortical evoked potentials.

Work carried out with the most modern and reliable EEG approach to questions related to attention, namely Grey Walter et al.'s Contingent Negative Variation (1964), is also devoid of any reference to the subject.

Changes in verbal communication attributable to traffic noise have also escaped examination, apart from the observations of Robinson (1969) and Beraneck (1954). The former found that a human voice could be clearly heard at a distance of 4 m when the background was not higher than 48 dB(A), while the latter calculated 40-45 dB(A) as the maximum ambient level compatible with the good understanding of radio and TV programmes. Lastly there are no references in the literature to changes in voice emission level in the presence of traffic noise.

RESEARCH AIMS AND TECHNICAL NOTES

The present research was directed to certain features of the effect of traffic noise on hearing, vegetative functions, and interpersonal relations. No attention has as yet been given to overall repercussions in the sense of "disturbance and annoyance" since this varies from one person to another. This side of the matter together with further investigation of the data so far obtained may be looked into later.

Traffic noise tapes were prepared by the G Ferraris National Electrotechnical Institute, Turin, Italy. The statistical data were processed by the Central Research Department of FIAT's Physical and Mathematical Laboratories. I should like to thank Drs. G P Galotto G Ruspa, M. Sattin and their assistants.

The following material was examined

a) ten one-minute recordings of daytime traffic noise, each taken at a different point in Turin
b) the first three recordings from a)
c) a two-hour recording consisting of 12 plays of the material in a)
d) three fifteen-minute recordings of night-time traffic noise, each taken at a different point in Turin and spaced out with a fifteen-minute silent interval
e) an acoustic signal from a Bettendorf reaction meter

Table 1 *Overall and synthetic data for the urban traffic noise used in the different experiments*

	min	L_m dB	L_{eq} dB	σ dB	L_m dB(A)	L_{eq} dB(A)	σ dB(A)
	0-10	88.8	89.4	2.35	71.6	73.3	3.54
b	0-3	89.2	89.7	2.30	71.4	72.1	.40
	0-120	86.8	87.6	3.75	74.1	76.2	4.60
	0-15	63.3	63.6	1.7	53.7	54.7	1.6
	15-30	87.7	89.3	4.1	74.9	76.9	4.3
d	30-45	63.4	63.8	1.6	54	54	0.6
	45-60	86.5	88.7	4.62	71.6	74	4.2
	60-75	63.9	64.2	1.65	54.2	54.2	0.86
	75-90	87.9	90.7	4.5	75.4	77.7	4.45
e	0-1	58.9	59.1	1.04	57.4	57.4	0.60

The following data were computed for each recording

1) equivalent sound level (L_{eq}) in dB and dB(A)
2) mean sound level (L_m), in dB and dB(A)
3) standard deviation (σ).

These data were calculated for each minute of the recording in the case of a) for each 10 minutes in the case of c) for each 15 minutes in the case of d). Table 1 gives the overall data picture. Reference is made to the data in

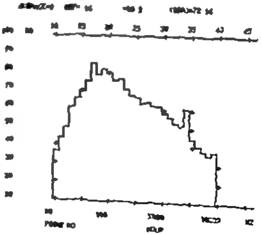

Fig. 1 Sound spectra at one-third of an octave for the 1st minute of tape).

noise and its characteristics. These workers felt that present traffic noise levels do not lead to significant TTS alterations, though they point out that no positive statement can be made since conclusive data are not yet available and the problem requires further investigation

Permanent threshold shift (PTS) changes have been examined only by Lierle & Reger (1958) Occupational deafness depending on the duration of exposure was observed by these workers in the majority of a group of tractor drivers

An equally small amount of attention has been directed to the question of whether the physiological falling-off of hearing with age (presbyacousis) is affected by traffic noise. Wakstein (1968) is of the opinion that such impairment can be accentuated and accelerated by traffic noise, even in subjects with occupational deafness as a result of its continuity

Though some doubts may be cast on the reliability of the personal data collected for their subjects, the findings of Jansen et al (1964), Rosen et al (1962, 1964) and Glorig (1957) are of interest. They showed that the older members of a Sudan tribe, the Mabaan, had distinctly better hearing than persons of the same age in Wisconsin New York Düsseldorf and Cairo whereas those members that had gone to live in Khartoum many years before could hear no better The Mabaan live in surroundings where the average background noise in about 30 dB

Effects on vegetative functions

Thiessen (1969 1970) studied the effect of traffic noise on sleep with recordings of lorries. He found that a mean noise level of 40 dB(A) woke 5 / of his subjects, whereas this figure rose to 30 / at 70 dB(A). Significant EEG signs of a marked fall in the depth of sleep were noted in 10 / and 60 / at these two levels respectively

Schieber et al. (1968) noted that low intensity traffic producing a mean noise level of 60 dB(A) had a much more significant effect on sleep rhythm and characteristics than very heavy traffic at 70 dB(A) It seems, therefore that occasional noise well above the mean background level has a greater effect on sleep than even louder but more continuous noise, presumably as the result of tolerance

Ossipov (1968) has shown that it takes about 1½ hr to get to sleep when traffic noise is 50 dB(A) Deep sleep periods are very short and subjects complain of marked tiredness on waking. He found that 35 dB(A) was an optimum level Twenty minutes was enough to ensure sleep and deep sleep periods lasted 2 2½ hr

Steinecke (1957) came to a similar conclusion though his research was conducted with simulated traffic noise, as did Scott (1972) in his study of EEG changes produced by noise during sleep

Other vegetative functions have received little attention Lang & Jansen (1967) observed increased autonomic system tone on exposure to noise levels comparable to those produced by road traffic. This was accompanied by mydriasis in relation to the intensity of the stimulus and its duration. They suggested that such level could reduce peristalsis and the secretion of saliva and gastric juice, and increase intracranial arterial pressure. These effects may be particularly marked when sudden loud noises are added to the background at irregular intervals Furthermore, Broadbent (1957) asserts that constant repetition of changes in sympathic tone may eventually lead to serious damage to health.

Effects on interpersonal relations

Here attention must first be directed to the modalities of reaction to stimuli of various kinds. One can either take an overall view or else examine the particular significance that given phenomena have in the performance of a reflex activity

As far as " behaviour " is concerned it must be noted that unusual reactions are more commonly attributable to sudden increases in background noise than to any given level No precise data are available for man Hoffmann & Flesher (1963) found that, in animals, reaction intensity is directly proportional to noise peak intensity and apparently unrelated to the intensity of the background noise This means that even the presence of a very high background level does not suffice to increase individual tolerance to sudden very loud noise

Reflex activity in response to light and sound stimuli in the presence of traffic noise appears

to have been neglected in the literature. The same appears to be true with respect to changes in cortical evoked potentials.

Work carried out with the most modern and reliable EEG approach to questions related to attention, namely Grey Walter et al.'s Contingent Negative Variation (1964), is also devoid of any reference to the subject.

Changes in verbal communication attributable to traffic noise have also escaped examination, apart from the observations of Robinson (1969) and Beraneck (1954). The former found that a human voice could be clearly heard at a distance of 4 m when the background was not higher than 48 dB(A), while the latter calculated 40-45 dB(A) as the maximum ambient level compatible with the good understanding of radio and TV programmes. Lastly there are no references in the literature to changes in voice emission level in the presence of traffic noise.

G P Galotto, G Ruspa, M Satun and their assistants.

The following material was examined

a) ten one-minute recordings of daytime traffic noise, each taken at a different point in Turin
b) the first three recordings from a)
c) a two-bour recording consisting of 12 plays of the material in a)
d) three fifteen-minute recordings of night-time traffic noise, each taken at a different point in Turin and spaced out with a fifteen-minute silent interval
e) an acoustic signal from a Bettendorf reaction meter

Table 1 *Overall and synthetic data for the urban traffic noise used in the different experiments*

	t	L_{eq} dB	L_m dB	σ	L_{eq} dB(A)	L_m dB(A)	σ dB(A)
a	0-10	88.5	89.4	2.35	71.6	73.3	3.54
b	0-3	89.2	89.7	2.30	71.4	72.1	2.40
c	0-120	86.8	87.6	3.75	74.1	76.2	4.60
	0-15	63.3	63.6	1.7	53.7	54.7	1.6
	15-30	87.7	89.3	4.1	74.9	76.9	4.3
d	30-45	63.4	63.8	1.6	54	54	0.6
	45-60	86.5	88.7	4.62	71.6	74	4.2
	60-75	63.9	64.2	1.65	54.2	54.2	0.86
	75-90	87.9	90.7	4.5	75.4	77.7	4.45
e	0-1	58.9	59.1	1.04	57.4	57.4	0.60

The following data were computed for each recording

1) equivalent sound level (L_{eq}) in dB and dB(A)
2) mean sound level (L_m) in dB and dB(A)
3) standard deviation (σ).

These data were calculated for *each minute* of the recording in the case of a), for each 10 minutes in the case of c), for each 15 minutes in the case of d). Table 1 gives the *overall* data picture. Reference is made to the data in

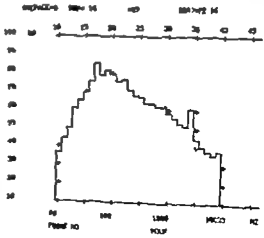

Fig. 1. Sound spectra at one-third of an octave for the 1st minute of tape a).

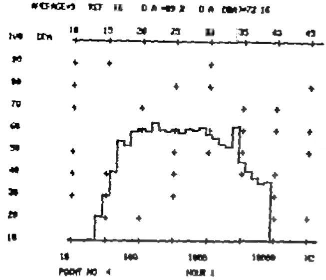

Fig 2 As last, weighted in accordance with the correction curve in dB(A).

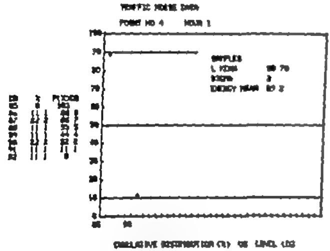

Fig 3 Cumulative distribution of sound level sin dB and print-out for the statistical values (1st minute of tape a)

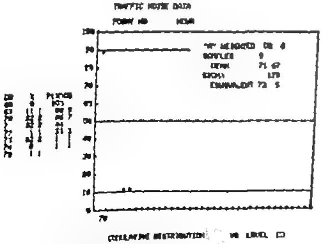

Fig 4 Cumulative distribution of sound levels in dB(A) and print-out for the statistical values (1st minute of tape a).

each paper where the findings are given in L and L_{eq}

Three diagrams were also prepared

1) sound spectra at one third of an octave
2) similar curves weighted in accordance with the correction curve in dB(A)
3) cumulative distribution of the sound level in dB and dB(A)

These diagrams were supplemented with a print-out giving the statistical values L_1, L_{10}, L_{50}, L_{90}. Figs 1-4 show the diagrams for the 1st minute of the tape referred to at a) *supra* by way of example

TEMPORARY THRESHOLD SHIFT (TTS) DUE TO EXPOSURE TO URBAN TRAFFIC NOISE

G Rossi M Scevola C Magliano

From the Department of Audiology University of Turin Turin Italy

SCOPE OF THE RESEARCH

Our aim was to see whether traffic noise (for details, see the next paragraph) altered the threshold level of the various frequencies of the tonal field and if so to what extent. Evaluation of the threshold is also described in the next paragraph

MATERIAL AND METHODS

Ten subjects of both sexes aged 10-25 yr with no prior history of even slight disease of the auditory apparatus were examined Air and bone thresholds at the frequencies normally employed in audiometry were established for each subject with an Amplifon 300 audiometer before commencing the experiment These were no higher than 5 dB Each subject was then trained in the technical features of the test The right ear was used in 5 subjects and the left ear in the other 5

The experiments were conducted with an automatic Grason-Stadler 1701 audiometer calibrated in HTL. A continuous tone in an ascending fashion was employed The frequency was increased by one octave per minute while intensity was decreased (or increased) at the rate of 2.5 dB per sec The tests were performed in a standard Amplifon G 5 silent booth measuring 240 × 240 × 240 cm itself placed in a room lined with sound absorbing panels.

The tone field (125-8000 Hz) was divided into three 2-octave bands 125-500 Hz 500-2000 Hz 2000-8000 Hz. The mean threshold for the frequencies in each band was obtained by adding the dB values of the bottom peaks in its trace and dividing the result by the number of peaks to two decimal places. Peaks above the 0 dB line were treated as negative and subtracted Computation of the dB value was facilitated by using a special piece of transparent paper with the audiogram 10 dB interval divided into 10 parts

Selection of the dB values for the bottom peaks as opposed to the top peaks or a mean of the two was decided upon after preliminary research (in the press) had shown that the values obtained when the subject presses the button in response to the sound signal are more constant and less subject to variations imposed by attention than those obtained when he no longer hears the sound and releases the button as well as being more constant than values representing the mean between the two

Road noise was taped through a Uher 4400 Report Stereo IC recorder into the circuit of an Amplaid 500 audiometer calibrated in dB SPL, and then to two loudspeakers set 25 cm from each ear of the subject, who was lying on a bed in the booth Before each experiment a Brüel & Kjaer 2209 phonometer fitted with a 1613 octave filter was used to check the intensity of the signal employed [redacted] the acoustic signal at the point occupied by the head of the subject

A 2 hr tape compiled by replaying a 10-min recording taken at ten different points in Turin

twelve times was used. Its characteristics were

L_m dB	L_{eq} dB	σ + dB
87 1	87.8	2.64
L_m dB(A)	L_{eq} dB(A)	σ + dB(A)
74 6	76.8	4 73

Following exposure to this road noise at its true intensity for 2 hr the test was repeated, on each subject and on different days, with attenuations of 5 10 15 and 20 dB

Thresholds were determined before each experiment, immediately after exposure to road noise, and 30' 60' 90' and 120' after the stimulation. Responses were recorded in the form of audiograms written by a Grason-Stadler 1701 X Y recorder connected to the audiometer

TTS was determined for each of the three 2-octave bands, and for each intensity of noise by calculating the difference between the thresholds at 0 30 60 90 and 120 minutes after exposure and the threshold observed before starting the experiment. An overall assessment of TTS behaviour was made by calculating, for each group of 10 values, for each of the 3 bands, and for each time, the mean value of the differences in threshold level with respect to the mean value of the pre-stimulation thresholds and the respective standard deviation (2 σ).

Since a subjective audiometric technique was used in assessing the threshold and its variations, a preliminary check was run to establish the validity of the method. For this purpose, a basal threshold was determined for each of the ten subjects and its variations over the experimental time period in the absence of road noise were noted, the aim being to see how far the threshold for each frequency band changed as a result of wearing the earphones or due to simple tiredness brought about by the length of the experiment.

The mean difference between the threshold levels observed at the start of the test and during this time period was calculated for each set of 10 data, plus the standard deviation (σ). This ga e a normal variation range for each frequency band and for each time period (shown by the dark bands in figs. 1 2 & 3). Values falling outside these limits could thus be considered as attributable to the acoustic stimulation.

RESULTS

Our overall results are illustrated in Table 1 and figs. 1 3 Mean TTS values were divided into three groups 1) means (with S D) that were outside the normal range in 100% of cases 2) means (with S.D) that were outside the normal range in at least 50% of cases 3) means (with S.D) that were outside the normal range in less than 50% of cases.

TTS behaviour in *relation to intensity* was examined first. It was found that values for the 125-500 Hz range fell into Group 1 when traffic noise was supplied at its real intensity as well as with attenuations of 5 dB and 10 dB, Group 3 values were obtained with attenuations of 15 dB and 20 dB

In the case of the 500-2000 Hz band, real intensity alone gave Group 1 values. Attenuations of 5 dB and 10 dB and of 15 dB and 20 dB gave Group 2 and Group 3 values respectively

Lastly real intensity and attenuations of 5 dB and 10 dB produced Group 2 values in the case of the 2000-8000 Hz band, whereas attenuations of 15 dB and 20 dB led to Group 3 values.

Assessment of TTS *in function of the time elapsed from the cessation of acoustic stimulation* showed that Group 1 in the case of the 125-500 and 500-2000 Hz bands values were obtained when traffic noise was supplied at its real intensity with Group 2 values for the 2000-8000 Hz band. Return to the normal range was observed within 90' 120' and 60' for the three bands respectively following cessation of the stimulus.

Attenuation of 5 dB gave Group 1 values for the first frequency band and Group 2 values for the remainder Recovery times were 60' for the first two bands and 30' for the third.

Attenuation of 10 dB resulted in Group 1 values for the first band only with Group 2 values for the other two bands. Recovery occurred after 30' in all three cases.

Attenuation of 15 dB ga e Group 2 values for the first band only with a recovery time of 30' In the case of the other two bands, TTS values already lay within the normal range at the end of the exposure to traffic noise. This was true for all three bands when an attenuation of 20 dB was applied.

CONCLUSIONS

With reference to the features of the noise employed, its duration, and the *method* used to evaluate TTS, our results make it clear that exposure to real traffic noise leads to a mean TTS shift of about 7 dB for frequencies of 125 to 2000 Hz, with recovery times of 90' in the case of the 125-500 Hz band and 120' for the 500-2000 Hz band. A shift of about 5 dB and a recovery time of 60' were noted for the 2000-8000 Hz band.

Attenuation of 5 dB resulted in a shift of about 5, 4 and 3 dB respectively for the three frequencies, followed by recovery times of 60', 60' and 30'. Attenuation of 10 dB led to shifts of about 4 dB, 2 dB and 2 dB, with recovery after 30' in all three cases.

15 dB and 20 dB attenuations meant that traffic noise failed to move TTS outside its normal spectrum of variation in the absence of acoustic stimulation.

Mean TTS following exposure to real road noise was slightly higher in the case of the 500-2000 Hz band, as opposed to the 125-500 Hz band, with recovery times of 120' and 90' respectively. For the 2000-8000 Hz band, mean TTS was lower than it was in the case of the other two bands, with a recovery time of 60'.

Bearing in mind the spectrum of the traffic noise employed and the well known features of TTS behaviour, our results appear to substantiate the *significance* of a hypothesis that could have been validly postulated in the first instance.

CHANGES IN STAPEDIUS REFLEX AMPLITUDE AND LATENCY FOLLOWING EXPOSURE TO URBAN TRAFFIC NOISE

G Rossi P Solero M Penna

From the Department of Audiology University of Turin, Turin, Italy

SCOPE OF THE RESEARCH

Bearing in mind what has so far been discovered with reference to the reflex dynamics of the stapedius, and the views put forward concerning its function an examination was made of changes in stapedius maximum contraction latency and amplitude due to fatigue produced by exposure to traffic noise for 3 minutes

It was felt that the results of the research might be of some assistance in determining the part played by the stapedius in protecting the inner ear from loud prolonged sounds.

MATERIAL AND METHODS

Seven subjects aged 19-26 yr with no history of diseases of the ear were examined Air and bone thresholds at the frequencies normally employed in audiometry were established for each subject before commencing the experiment An Amplifon 300 audiometer was used for this purpose and the right and left ear were tested in 4 and 3 subjects respectively in a silent room lined with sound-absorbing panels Thresholds were no higher than 5 dB

Comparison was made between changes in latency and amplitude of the maximum contraction of the stapedius, before and after exposure to traffic noise for 3 min and at 2 intervals for 10 subsequently

A tape consisting of three 1 minute recordings of daytime noise taken at different points of Turin was used Its characteristics were

L_m dB	L_{eq} dB	$\sigma +$ dB
89 2	89 7	2.3
L_m dB(A)	L_{eq} dB(A)	$\sigma +$ dB(A)
71 4	71 1	2 4

This noise was fed through a Uher 4400 stereo I C recorder into the circuit of an Amplaid 500 audiometer calibrated in dB SPL, and into the headphone worn by the subject via an Amplaid Z impedance meter

Stapedius maximum contraction amplitude and latency and the changes in these parameters brought about by traffic noise were evaluated with the aid of a pure 1000 Hz tone at 100 dB lasting 1 sec. Since the stapedius reflex usually occurs in response to sounds 70-75 dB higher than the threshold of the pure tone employed as stimulus, an intensity value of 100 dB was used to ensure that the response obtained before exposure to noise would be of sufficient amplitude to allow the changes induced by muscle fatigue to be reliably determined

Amplitude was recorded on graph paper (in mm) by means of an X Y Grason-Stadler recorder connected to the impedance meter At the same time, latency was evaluated in msec by inserting the pure tone and the response into the circuit of a 5103 N Tektronix oscilloscope calibrated at 200 msec, followed by photographic recording with a Polaroid Tektronix C_4 oscilloscope camera. Amplitude was arbitrarily measured in mm For greater ac

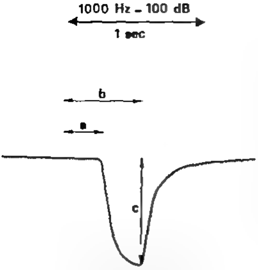

Fig. 1. a) time elapsed between presentation of the stimulus and beginning of reflex contraction of the stapedius. b) latency of maximum contraction. c) amplitude of maximum contraction.

curacy the graphs were enlarged 10 times with a Plawa epidiascope and values were read with a ruler gratuated in mm (fig. 1).

Amplitude and latency were evaluated immediately prior to exposure. At the end of the exposure (3'), the pure tone was immediately switched through to the subject's ear and then again at 2' intervals.

Following exposure to traffic noise at its true intensity each subject heard the same recording on different days with an attenuation of 5, 10, 15, 20 and 25 dB. Noise intensity was determined with a Brüel & Kjaer 2209 phonometer fitted with a 1613 octave filter before the commencement of each experiment.

Before and after exposure to real or attenuated traffic noise, and at the end of each experiment, drumhead compliance in the absence of the reflex was evaluated with an intracavity pressure of 200 mm H_2O. A tympanometric curve was also elaborated on each occasion to assess the give in the absence of the reflex and with the membrane slack. The values obtained were in all cases the same as those observed before exposure to noise.

Both before and at the end of each experiment, a linear relationship was always noted between the volumetric variations of a perfectly sealed tester calibrated in cm³ and the shift amplitude of the pen connected to the impedance meter. This check on the percent evaluation of changes in stapedius contraction latency and amplitude after exposure to noise was rendered necessary by the observation that these parameters were not identical in the tested subjects before exposure.

The method employed was checked before commencing the experiment to assess individual variations in stapedius response in function of the proposed time pattern in the absence of noise. Since the biological phenomenon involved could well be affected by extraneous influences of undetermined entity, variations of some kind were, indeed, to be expected.

A stapedius reflex was therefore elicited from each subject in the absence of traffic noise on 3 occasions, on 3 successive days, using the proposed experimental pattern: initially, after 3

and then at 2 intervals for 10 Latency and amplitude were determined on each occasion.

The mean findings and their standard deviation (2 σ) were used to establish the normal variation ranges for these 7 subjects at each experimental time (shown as dark bands in figs. 2 13)

RESULTS

These are illustrated in figs. 2 to 13 Values obtained before exposure to noise obviously differed from one subject to another Absolute individual and overall variations were clearly of no assistance in evaluating the phenomenon under examination and use was therefore made of percent only so that a reliable and meaningful point of comparison could be obtained

Percent changes in amplitude and latency were referred to the overall values for these parameters, i e the means (and 2 σ) determined before the test.

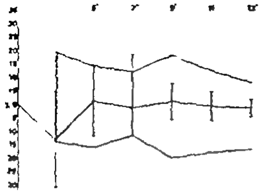

Fig 11 As last, with attenuation of 15 dB.

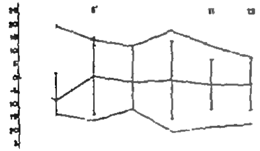

Fig 12. As last, with attenuation of 20 dB.

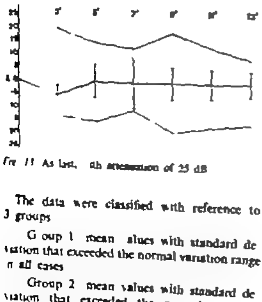

Fig 13 As last, with attenuation of 25 dB

The data were classified with reference to 3 groups

Group 1 mean values with standard deviation that exceeded the normal variation range in all cases

Group 2 mean values with standard deviation that exceeded the normal variation range in at least 50 of cases

Group 3 mean values with standard deviation that exceeded the normal variation range in less than 50 of cases.

In the case of *latency of maximum contraction of the stapedius* exposure to traffic noise for 3 at its true intensity led to a mean percent reduction of 5.32 ± 3.44 msec. In more than 50 of cases, this reduction exceeded the normal variation range. At the end of the first three 2′ intervals, this pattern was unchanged. At the 11th and 13th minutes, normalisation was apparent. There were no Group 1 values.

An attenuation of 5 dB in noise intensity was accompanied by Group 3 values after 3 and 5′ followed by normalisation. Further decibel reductions led to further Group 3 values. In most cases, indeed, these were within the normal range.

Exposure for 3 to unattenuated traffic noise was followed by Group 2 values and a mean percent reduction of 36.01 ± 27.36 in *amplitude of maximum contraction of the stapedius* This pattern persisted until the 9th minute, followed by normalisation.

An attenuation of 5 dB again led to Group 2 values after 3 After 5 and 7′ values were in Group 3 Values falling within the normal range were noted at 11 and 13

Values were in Group 2 after 3 with an attenuation of 10 dB After 5 percent variations within the normal range appeared, whereas mean values were in Group 3 after 7′ and 9 and within the normal range after 11 and 13

A reduction of 15 dB led to Group 3 values after 3 and 7′ with percent variations within the normal range at the 5th, 9th, 11th and 13th minutes.

Apart from Group 3 values after 7′ with 20 dB attenuation, percent changes were within the limits of normal at all times when the intensity of traffic noise was reduced by 20 dB and 25 dB.

It will be seen that no Group 1 mean values were observed under any of the experimental conditions.

CONCLUSIONS

In the case of *amplitude of maximum contraction of the stapedius* our results make it clear that this parameter varies over an extremely wide range, even under normal conditions, i.e. in the absence of fatigue caused by traffic noise. Stress may be laid on this fact, since it offers real

evidence of a phenomenon whose features and meaning are not fully established. Suffice it to recall here that reflex contraction of the stapedius cannot even be detected in about 1 of subjects, that some persons can contract the muscle voluntarily (Møller 1974), and that the characteristics of contraction itself would appear to be related to attention (Brasher et al., 1969)

Exposure to real traffic noise leads to an approximately 36 / reduction in amplitude after 3 Attenuation by stages is followed by a gradual fall in this figure. A reduction of 20 and 25 dB in fact, results in the observation of values falling within the normal range.

The situation immediately after the 3 exposure period is of interest, as it is marked by a rebound. At the end of the first 2 period of silence, i.e. 5 after the start of the experiment, the reduction in amplitude is less than that at 7 irrespective of whether real or attenuated traffic noise is employed Subsequently the return to normal values is a direct function of the degree of attenuation employed This means that while fatigue is at its maximum after 3 and can even be induced when traffic noise is diminished by 15 dB, its subsequent elimination is not linear but is marked by a rebound from nearly normal values to levels that are, however a long way from those observed at the end of the 3 exposure period

Turning now to *latency of maximum contraction of the stapedius* our findings show that exposure to traffic noise at its real intensity for 3 is responsible for a mean reduction of about 5 /. Attenuation of 5 dB is accompanied by the same result though the percent incidence is less. Return to what may be considered the normal range of variation occurs quickly and appears devoid of linearity at least under our experimental conditions.

Depressed latency values, on the other hand, may be more apparent than real, since they may be a direct expression of the reduction in amplitude induced by fatigue. Indeed, no statistically significant difference in values was noted after exposure to traffic noise in the *time elapsed between presentation of the stimulus and the beginning of reflex contraction of the stapedius* Virtually the same data were constantly observed for each subject and need not be set out in detail here. It may well be that reduction in latency of maximum contraction is entirely dependent on reduction in amplitude. The former however falls by only 5 as against the 36 drop in amplitude. This in itself is enough to show that the maximum contraction of the fatigued muscle, albeit reduced in amplitude, is reached almost as quickly as under normal conditions. Changes in amplitude and latency times of the maximum contraction of the stapedius may offer a guide to the effectiveness of the protection thought to be given to the inner ear by the stapedius muscle in normal situations and after exposure to fatiguing noise.

CHANGES IN THE TIME OF REACTION TO LIGHT AND SOUND SIGNALS IN THE PRESENCE OF URBAN TRAFFIC NOISE

G Rossi C. Magliano M Scevola

From the Department of Audiology University of Turin, Turin, Italy

SCOPE OF THE RESEARCH

Motor activity takes place via pre-established nervous pathways that can translate into movement a response or reaction to a stimulus received by the sensory organs.

The time required to react to a given stimulus may be affected by attention, habituation and fatigue. A competitive stimulus of the same nature as the first may also have the same effect on the complex mechanism triggering the reaction. Both signals use the same nervous pathways to reach the central system Interference with the performance of motor activity following reception of the meaningful signal is inevitable.

A situation of this kind occurs every time a motor activity in response to an acoustic signal is required in noisy surroundings. Traffic noise is an example of a competitive stimulus. The almost continuous interference that it creates is an important object of study

In this connection, a useful comparison can be made with the pattern followed by motor reaction time in response to a light signal, since this employs a different route to noise on its path to the central system. No interference should therefore take place between a significant (*light*) and a competitive (traffic noise) stimulus in such conditions.

This paper investigates changes in the reaction time required for the performance of a simple and a complicated movement following a light or an acoustic stimulus presented at the same time as road noise.

MATERIAL AND METHODS

Ten subjects aged 20-25 yr with normal hearing and no history of auditory disease were used.

Air and bone thresholds at the frequencies normally employed in audiometry were established for each subject with an Amplifon 300 audiometer before commencing the experiment thresholds were no higher than 5 dB. The experiment was done with the subject lying on a bed inside a standard *Amplifon G 5 silent* booth measuring 240 × 240 × 240 cm with soft lighting. This booth was placed in a room lined with sound-absorbing panels. Reaction times in the presence of traffic noise were evaluated with respect to a light and an acoustic stimulus supplied by a cassette connected to an original Bettendorf reaction meter calibrated in centiseconds. In the case of the light stimulus, the cassette was placed on the wall in front of the subject s head and about 2 m from his eyes. For the acoustic stimulus, the cassette was set behind the head, 10 cm above its vertex and 30 cm from each ear A recording taken at the place occupied by each ear showed the sound signal to have the following characteristics

L_m dB	L_{eq} dB	$\sigma +$ dB
58.9	59 05	1 04
L_m dB(A)	L_{eq} dB(A)	$\sigma +$ dB(A)
57 4	57.4	0 60

On the appearance of either the light or the sound signal, the subject was required to move his right hand to break a ray of light striking

evidence of a phenomenon whose features and meaning are not fully established Suffice it to recall here that reflex contraction of the stapedius cannot even be detected in about 1 / of subjects, that some persons can contract the muscle voluntarily (Moller 1974) and that the characteristics of contraction itself would appear to be related to attention (Brasher et al., 1969)

CHANGES IN THE TIME OF REACTION TO LIGHT AND SOUND SIGNALS IN THE PRESENCE OF URBAN TRAFFIC NOISE

G Rossi, C. Magliano M Scevola

From the Department of Audiology University of Turin, Turin, Italy

SCOPE OF THE RESEARCH

Motor activity takes place via pre-established nervous pathways that can translate into movement a response or reaction to a stimulus received by the sensory organs.

The time required to react to a given stimulus may be affected by attention, habituation and fatigue. A competitive stimulus of the same nature as the first may also have the same effect on the complex mechanism triggering the reaction. Both signals use the same nervous pathways to reach the central system. Interference with the performance of motor activity following reception of the meaningful signal is inevitable

A situation of this kind occurs every time a motor activity in response to an acoustic signal is required in noisy surroundings. Traffic noise is an example of a competitive stimulus. The almost continuous interference that it creates is an important object of study

In this connection, a useful comparison can be made with the pattern followed by motor reaction time in response to a light signal, since this employs a different route to noise on its path to the central system. No interference should therefore take place between a significant (light) and a competitive (traffic noise) stimulus in such conditions.

This paper investigates changes in the reaction time required for the performance of a simple and a complicated movement following a light or an acoustic stimulus presented at the same time as road noise.

MATERIAL AND METHODS

Ten subjects aged 20-25 yr with normal hearing and no history of auditory disease were used.

Air and bone thresholds at the frequencies normally employed in audiometry were established for each subject with an Amplifon 300 audiometer before commencing the experiment thresholds were no higher than 5 dB The experiment was done with the subject lying on a bed inside a standard Amplifon G 5 silent booth measuring 240 × 240 × 40 cm with soft lighting. This booth was placed in a room lined with sound-absorbing panels. Reaction times in the presence of traffic noise were evaluated with respect to a light and an acoustic stimulus supplied by a cassette connected to an original Bettendorf reaction meter calibrated in centiseconds. In the case of the light stimulus, the cassette was placed on the wall in front of the subject's head and about 2 m from his eyes. For the acoustic stimulus, the cassette was set behind the head, 10 cm above its vertex and 30 cm from each ear A recording taken in the place occupied by each ear showed the sound signal to have the following characteristics

L_m dB	L_{eq} dB	σ ± dB
58.9	59.05	1.04
L_m dB(A)	L_{eq} dB(A)	σ ± dB(A)
57.4	57.4	0.60

On the appearance of either the light or the sound signal, the subject was required to move his right hand to break a ray of light striking

a photoelectric cell directly connected to the reaction meter

Two types of motor reaction were investigated a simple reaction and a complicated reaction In the first case, the subject lay on the bed with his right arm extended along his side and his fingers outstretched The reaction required was a simple flexion of the forearm without moving the elbow The tips of the fingers cut the ray of light passing above and across the subject at the top of their arc. Fifty stimuli were supplied in 3 at randomised intervals to prevent habituation

The same procedure was followed for the complicated reaction In this case, however the subject s hand had to touch his left shoulder the light ray ran paralled to his left flank and was cut when the fingertips began their descent towards the shoulder

Road noise was supplied by means of a tape consisting of three 1 minute recordings taken at different points of Turin Its characteristics were

L_m dB	L_{eq} dB	$\sigma +$ dB
89 2	89 7	2.3
L_m dB(A)	L_{eq} dB(A)	$\sigma +$ dB(A)
71 4	72.1	2.4

This noise was fed through a Uher 4400 stereo I C recorder to the circuit of an Amplaid 500 audiometer calibrated in dB SPL, and then to two loudspeakers set 25 cm from each ear Before commencing each experiment, a Brüel & Kjaer 2209 phonometer fitted with a 1613 octave filter was used to check the intensity of the traffic noise at the height of each ear

Following exposure to road noise at its true intensity attenuations of 5 10, 15 and 20 dB were introduced A series of 50 tests occupying 3 was run at intervals of 3 (with the subject at rest on the bed) for each intensity level The arithmetic mean of each set of 50 values was used as the mean reaction time and compared with a similar mean obtained for the light or acoustic stimulus in the absence of road noise This mean was derived from 25 values obtained before the exposure to road noise at its true intensity and 25 after exposure with an attenuation of 20 dB Both of these series were obtained with 25 light or sound signals supplied at randomised intervals over a period of 90

This method of determining reaction times did not neglect the part that tiredness or habituation might play even in the case of randomised signals towards the end of each experiment.

S D s (2 σ) in the absence of traffic noise were calculated for each subject to provide a normal range of reaction times for the significant signal The difference between these values and those observed during exposure to road noise could thus be attributed to interference on the part of such noise with the mechanism required for performance of the simple and complicated reactions.

Overall evaluation of the results was made in the light of the arithmetic means of the data obtained from the 10 subjects in each experimental situation

RESULTS

Table 1 and figs 1 3 and Table 2 and figs. 4-6 show the results for the simple and complicated reaction respectively Reaction times varied from one subject to another and their single and total absolute values were of little significance Meaningful comparisons were thus made by using percent variations.

In the absence of road noise, all 10 subjects reacted much more quickly to the acoustic signal mean times of 24 csec and 34 csec for the simple and complicated reaction respectively as opposed to 29 csec and about 42 csec (reductions of about 18 % and 24 %) when the light stimulus was used

Exposure to real and attenuated road noise made no significant difference to the mean reaction time for the simple reaction following the light signal. Values lay within the spectrum of variation observed in the absence of such noise

When the acoustic signal was given however exposure to real road noise led to an increase of about 24 Attenuation cut back this increase to about 18 % 12 %, 9 and 3 for 5 10 15 and 20 dB reductions in intensity respectively

The picture was the same for the complicated reaction Real and attenuated road noise made no real difference when the light signal was used With the acoustic signal real noise

led to an increase of about 22 %, and this was reduced to about 16 %, 12 %, 10 % and 4 % with increasing attenuation.

CONCLUSIONS

The first point to emerge from our results is less time is required for the execution of either a simple or a complicated motor reaction in response to an acoustic as opposed to a light signal. No physical or anatomical explanation can be advanced for the constant observation of this difference in all 10 subjects. It is probably the outcome of a difference in attention referable to the spatial features associated with the information that the two stimuli provide.

It is, in fact, obvious that the light stimulus reaches the receptor solely from a well defined visual field that is both in front of us and known to us, whereas a sound can reach our ears from any point of space, even from behind us. This lack of precise definition of the acoustic source probably serves to accentuate our attention prior to the emission of a known and awaited stimulus. This, *in turn*, has a considerable effect on the time required for the ensuing simple or complicated *response reaction*.

Road noise did not alter the mean reaction time in the case of light *stimuli*. *Here* the meaningful light signal and the competing traffic noise were gathered by different receptors and reached the centres via separate and distinct nervous pathways, so that the anatomical substrate for interference was not present.

When, on the other hand, the two signals were gathered by the same receptor and reached the centres via the same pathway a situation arose in which the mean simple and complicated motor reaction times increased by comparison with those for the response to the meaningful signal alone.

When real road noise was used, this increase was as much as 20 %. The standard deviation reflects the discontinuity of traffic noise and the different ways in which interference between a meaningful and a competing signal may take place.

Attenuation through the 5 to 20 dB range resulted in gradual decreases in this percentage that were almost the same for the simple and the complicated reaction, though it was not suppressed completely

These findings are the expression of interference between two signals, apparently in proportion to the intensity of the competing signal. This interference, *in its turn*, is an expression of the difficulties encountered by the meaningful signal in reaching the centres owing to "partial congestion of the line". It is not eliminated entirely even when the competing signal is attenuated by as much as 20 dB, though it may be supposed that further attenuation would have this effect. This possibility however was not investigated, because it would have involved too distant a departure from real conditions.

CHANGES IN CORTICAL RESPONSIVITY TO MULTISENSORIAL STIMULI DURING EXPOSURE TO URBAN TRAFFIC NOISE

B Bergamasco M Gilli G Rossi

From the Department of Audiology and the Nervous and Mental Diseases Clinic University of Turin Turin, Italy

SCOPE OF THE RESEARCH

As everyone knows, noise disturbs psychic activity On the other hand no attempt has yet been made to determine the neurophysiological mechanisms whereby noise produces its supposed pathogenic action in man. The scanty data in the literature are almost solely confined to the effect noise has on sleep (Rechtschaffen et al 1966 Alexander 1972 a b).

This paper deals with preliminary data collected in an examination of the effect of traffic noise on cortical responsivity to acoustic and visual stimuli

MATERIAL AND METHODS

EEG potentials elicited by acoustic stimuli were measured during several sessions on 20 normal subjects aged 18-35 yr using needle electrodes with unipolar leads in the scalp and a reference electrode on the mastoid during repose and during 10 exposure to road noise (RN). Stimuli and processing of the responses were carried out with a Medelec Amplaid ERA EcoG complex, consisting of an acoustic stimulus generator a 4-track averager and an acoustic generator console for the elaboration of tones and noise. Two loudspeakers 50 cm from the left and right of the subject s head were used to furnish the acoustic signals in a soundproof recording room The acoustic signal was an 80 dB SPL click while an 0 3 J flash was generated by a stroboscope triggered by the computer

A tape consisting of ten 1 minute recordings of daytime RN each taken at different points

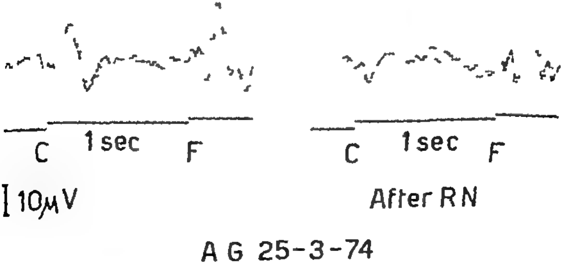

Fig 1 EAP (C) and EVP (F) (mean of 30 values) in the same subject during repose (left) and a few seconds before the termination of a 10' RN tape (right). *C indicates the click and F the flash. Note the large change in EAP and* steady EVP

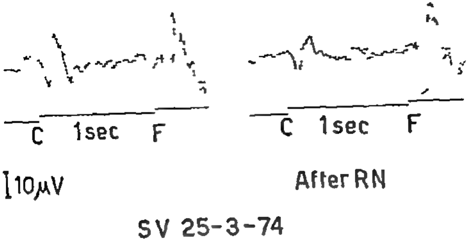

FIG. 2A

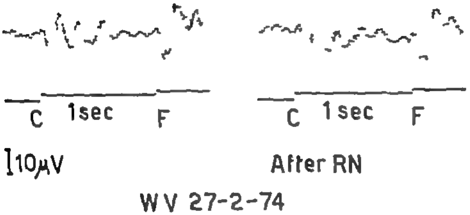

FIG. 2B

Fig. A) EAP (C) and EVP (F) in the same subject during repose (left) and shortly before the termination (right) of 10 RN tape. Each value is the mean of 50 responses. Note the fall in EAP amplitude and scant change in EVP. B) As last, in different subject.

of Turin, was used. Its characteristics were

L_m dB	L_{eq} dB	$\sigma \pm$ dB
88.8	89.4	2.35
L_m dB(A)	L_{eq} dB(A)	$\sigma \pm$ dB(A)
71.6	73.1	3.54

This noise was used at its real intensity which was assessed by a Brüel & Kjaer 2209 phonometer fitted with a model 1613 octave filter placed at the point occupied by the subject's head.

RN was fed through a Uher 4400 stereo I.C. recorder and then into the recording room via the complex consolle as already described. Following recordings during repose, acoustic and visual responses were taken during and shortly before stopping the tape. Each stimulus pair consisted of a click followed after 1 s by the flash and was fed to the subject at randomised intervals. An average value from 50 responses was used. The p_1-n_2 wave (positive and negative deflections with 80-120 msec latency) was employed in assessment of the elicited acoustic potential (EAP) peak-to-peak amplitude, since these deflections were absolutely constant in all subjects and are free of any myogenic com-

ponent (Cordove et al 1969 Picton et al 1974) The V wave amplitude according to Gastaut (Bergamini and Bergamasco 1967) was used for the elicited visual potential (EVP)

RESULTS

A marked reduction in EAP amplitude was noted in all subjects a few seconds before the tape finished (figs. 1 and 2) whereas no signi ficant change in EVP appeared

The mean EAP for the series was 22.5 μV during repose and 13 75 μV a few seconds before the tape finished i e a difference of 40 6 / (Table 1) These data were statistically significant.

Table 1 *Mean μV value of EAP wave (p_2n_2) during repose and at conclusion of RN for 10' and percent reduction Ranges in brackets*

During repose	22.5	(R 16.1 28 3)
At conclusion of RN for 10	13 75	(R 10.2 20.3)
Percent reduction	40.6	(R 32.2 60 1)

No particular difference in EVP amplitude was observed under these conditions (26 8 μV during repose 25 75 μV after RN) Some sub jects *indeed displayed an increase in amplitude* after exposure to RN

CONCLUSIONS

A dramatic fall in EAP and no change in EVP are the consequences of 10 exposure to RN This difference is open to three possible expla nations

1) activation by RN of the ascending reticular system and reduction in cortical response amplitude and EEG desynchronization due to occlusive convergence in accordance with the data of Bremer (1958) and Naquet et al (1960)
2) cochlear inhibition on the part of centrifugal acoustic pathways in accordance with the experimental data collected by Galambos (1956)
3) cortical inhibition

Possibility 1) is ruled out by the absence of any fall in EVP after RN Moreover EEG desynchronization disappears a few minutes later The second possibility is at present devoid of supporting evidence while further data are necessary before accepting the possibility of cortical inhibition Some of these (behaviour of the contingent negative variation during RN) are been investigated (see next paper)

All that can be said so far is that changes in cortical responsitivity to multisensorial sti muli after exposure to RN concern the acoustic stimulus only i e. sensoriality related to RN itself

BEHAVIOUR OF CNV DURING EXPOSURE TO URBAN TRAFFIC NOISE

B. Bergamasco, P Benna, A. M Covacich, M Gilli, G Rossi

From the Department of Audiology and the Nervous and Mental Diseases Clinic University of Turin, Turin, Italy

SCOPE OF THE RESEARCH

In previous research, we observed that during administration of road noise modifications take place in cortical response that exclusively involve evoked acoustic potential, whereas responses evoked by other sensorial modalities show no variation. The clear-cut reduction in evoked response may be interpreted as the consequence of noise-induced neuronal occlusion (noise occupies neurones at the expense of the acoustic stimulus and not of other stimuli evoking cortical potential). Our experimental findings confirm the masking effect of noise on verbo-acoustic communications and it is notorious that noise disturbs these as early as 40 dB and makes them impossible beyond 80-90 dB

The present paper examines the problem of whether road noise modifies cortical responsiveness t psychological as well as to sensorial stimuli The Contingent Negative Variation has been used as a parameter for this reason.

MATERIAL AND METHODS

The research was carried out on 1 volunteers of both sexes and aged between 21 and 33 yrs. Their hearing was normal. The Contingent Negat e Variation (CNV) was recorded in cond tions of normal quiet background and during administration of road noise (RN).

The road noise employed consisted of 10 recordings of 1 each made at 10 different points in Turin during the hours of daytime traffic The following road noise data, in terms of L_m and L_{eq} were adopted

L_m dB	L_{eq} dB	$\sigma +$ dB
88.8	89 4	2.35
L_m dB(A)	L_{eq} dB(A)	$\sigma +$ dB(A)
71 6	73 1	3.54

The road noise was used with real intensity characteristics valued by means of a Brüel and Kjaer mod. 2209 phonometer with mod 1613 octave filter at the subject s head.

The tape was played on a Uher 4400, Report Stereo 1 C, recorder and the road noise was then put through an Elit 815 audiometer into a free field from two speakers half a meter apart on the right and left of the subject.

CNV was recorded in traditional fashion The subject was laid on a bed in a twilit room with a sound-proofed flasher 40 cm from his eyes (flash 0.3 J) while a pair of loud-speakers 10 cm right and left of his head and connected to an acoustic generator supplied an 80 dB SPL click. The flasher and acoustic generator were connected with the central stimulus programmer Monopolar frontal EEG recording was carried out by means of needle-electrodes and the cerebral bioelectric lead was connected to an O.T.E. 1172 Neuroaverager This provides correlated averages it possesses an analogic-digital interface that makes it possible to choose between automatic and manual operation. Manually each sweep containing the CNV can be viewed for 3 those spoiled by

ponent (Cordove et al 1969 Picton et al 1974) The V wave amplitude according to Gastaut (Bergamini and Bergamasco 1967) was used for the elicited visual potential (EVP)

RESULTS

A marked reduction in EAP amplitude was noted in all subjects a few seconds before the tape finished (figs. 1 and 2) whereas no significant change in EVP appeared

The mean EAP for the series was 22.5 μV during repose and 13 75 μV a few seconds before the tape finished i e a difference of 40 6 % (Table 1) These data were statistically significant.

Table 1 *Mean μV value of EAP wave (p_3-n_3) during repose and at conclusion of RN for 10 and percent reduction Ranges in brackets*

During repose	2..5 (R 16.1 28.3)
At conclusion of RN for 10	13 75 (R 10.2 20.3)
Percent reduction	40.6 (R 32.2 60 1)

No particular difference in EVP amplitude was observed under these conditions (26 8 μV during repose 25 75 μV after RN) Some subjects indeed displayed an increase in amplitude after exposure to RN

CONCLUSIONS

A dramatic fall in EAP and no change in EVP are the consequences of 10 exposure to RN This difference is open to three possible explanations

1) activation by RN of the ascending reticular system and reduction in cortical response amplitude and EEG desynchronization due to occlusive convergence, in accordance with the data of Bremer (1958) and Naquet et al (1960)
2) cochlear inhibition on the part of centrifugal acoustic pathways, in accordance with the *experimental data collected by Galambos* (1956)
3) cortical inhibition

Possibility 1) is ruled out by the absence of any fall in EVP after RN Moreover EEG desynchronization disappears a few minutes later The second possibility is at present devoid of supporting evidence while further data are necessary before accepting the possibility of cortical inhibition Some of these (behaviour of the contingent negative variation during RN) are been investigated (see next paper)

All that can be said so far is that changes in cortical responsivity to multisensorial stimuli after exposure to RN concern the acoustic stimulus only i e sensoriality related to RN itself

BEHAVIOUR OF CNV DURING EXPOSURE TO URBAN TRAFFIC NOISE

B Bergamasco, P Benna, A. M Covacich M Gilli, G Rossi

From the Department of Audiology and the Nervous and Mental Diseases Clinic University of Turin, Turin, Italy

SCOPE OF THE RESEARCH

In previous research, we observed that during administration of road noise modifications take place in cortical response that exclusively involve evoked acoustic potential whereas responses evoked by other sensorial modalities show no variation. The clear-cut reduction in evoked response may be interpreted as the consequence of noise induced neuronal occlusion (noise occupies neurones at the expense of the acoustic stimulus and not of other stimuli evoking cortical potential). Our experimental findings confirm the masking effect of noise on verbo-acoustic communications and it is notorious that noise disturbs these as early as 40 dB and makes them impossible beyond 80-90 dB.

The present paper examines the problem of whether road noise modifies cortical responsiveness to psychological as well as to sensorial stimuli The Contingent Negative Variation has been used as a parameter for this reason.

MATERIAL AND METHODS

The research was carried out on 12 volunteers of both sexes and aged between 21 and 33 yrs. Their hearing was normal. The Contingent Negative Variation (CNV) was recorded in conditions of normal quiet background and during administration of road noise (RN).

The road noise employed consisted of 10 recordings of 1 each made at 10 different points in Turin during the hours of daytime traffic. The following road noise data, in terms of L_{50} and L_{eq} were adopted

L_{50} dB	L_{eq} dB	$\sigma +$ dB
88.8	89 4	2.35
L_{50} dB(A)	L_{eq} dB(A)	$\sigma +$ dB(A)
71 6	73 1	3.54

The road noise was used with real intensity characteristics valued by means of a Brüel and Kjaer mod. 2209 phonometer with mod. 1613 octave filter at the subject s head.

The tape was played on a Uher 4400 Report Stereo I C, recorder and the road noise was then put through an Elit 815 audiometer into a free field from two speakers half a meter apart on the right and left of the subject.

CNV was recorded in traditional fashion. The subject was laid on a bed in a twilit room with a sound-proofed flasher 40 cm from his eyes (flash 0.3 J) while a pair of loud-speakers 10 cm right and left of his head and connected to an acoustic generator supplied an 80 dB SPL click. The flasher and acoustic generator were connected with the central stimulus programmer Monopolar frontal EEG recording was carried out by means of needle-electrodes and the cerebral bioelectric lead was connected to an O T.E. 1172 Neuroaverager This provides correlated averages it possesses an analogic-digital interface that makes it possible to choose between automatic and manual operation. Manually each sweep containing the CNV can be viewed for 3 those spoiled by

ponent (Cordove et al 1969 Picton et al 1974) The V wave amplitude according to Gastaut (Bergamini and Bergamasco 1967) was used for the elicited visual potential (EVP)

RESULTS

A marked reduction in EAP amplitude was noted in all subjects a few seconds before the tape finished (figs 1 and 2) whereas no significant change in EVP appeared

The mean EAP for the series was 22.5 μV during repose and 13 75 μV a few seconds before the tape finished i e a difference of 40 6 / (Table 1) These data were statistically significant.

Table 1 *Mean μV value of EAP wave (p_3 n_3) during repose and at conclusion of RN for 10 and percent reduction Ranges in brackets*

During repose	22.5 (R 16 1 28.3)
At conclusion of RN for 10'	13 75 (R 10.2 20.3)
Percent reduction	40 6 (R 32.2 60.1)

No particular difference in EVP amplitude was observed under these conditions (26 8 μV during repose 25 75 μV after RN) Some subjects, indeed displayed an increase in amplitude after exposure to RN

CONCLUSIONS

A dramatic fall in EAP and no change in EVP are the consequences of 10 exposure to RN This difference is open to three possible explanations

1) *activation by RN of the ascending reticular* system and reduction in cortical response amplitude and EEG desynchronization due to occlusive convergence in accordance with the data of Bremer (1958) and Naquet et al (1960)
2) cochlear inhibition on the part of centrifugal acoustic pathways, in accordance with the experimental data collected by Galambos (1956)
3) *cortical inhibition*

Possibility 1) is ruled out by the absence of any fall in EVP after RN Moreover EEG desynchronization disappears a few minutes later The second possibility is at present devoid of supporting evidence, while further data are necessary before accepting the possibility of cortical inhibition Some of these (behaviour of the contingent negative variation during RN) are been investigated (see next paper)

All that can be said so far is that changes in cortical responsivity to multisensorial stimuli after exposure to RN concern the acoustic stimulus only i e sensoriality related to RN itself

[Fi]g. 2. CNV (averaging of 25 responses) obtained in the same subject during normal quiet background (continuous [lin]e) and during RN administration (interrupted line). Note the greater amplitude of the CNV recorded during RN.

[v]ariations were not uniform. One group (A, [T]able 1) presented a fall in CNV amplitude [d]uring RN (fig. 1), another group (B, Table 1) a increase (fig. 2), while in two cases (C, [T]able 1), no modifications were observed at all.

It goes without saying that statistical analysis [o]f the variation in CNV amplitudes of the [g]roup as a whole did not show any significance (P < 0.30). Nor was the CNV amplitude fall observed in four subjects (group A, Table 1) during administration of a quiet background statistically significant (P < 0.10). Only in group B of Table 1 (a group in which CNV presented increased amplitude during RN administration) was there any statistical significance (P < 0.01).

CONCLUSIONS

The findings show clearly that RN acts differently on the psychoattentive functions of the various subjects.

Moreover it is well known that the subjective sensation of "unpleasantness irritation" induced by noise does not arise at any specific intensity level but within ranges depending on the subject (between 40 and 90 dB according to Kryter, 1970). The intragroup variability of CNV amplitude as observed by us confirms the above. But it is even more interesting to note that in a certain number of subjects CNV amplitude falls and in others it increases, as if to suggest that in the former RN irritates the psychoattentive processes set in motion by CNV while in the latter it facilitates them. Clearly the reason for this difference must be sought in the way in which noise triggers basic psychological mechanisms, in other words, in the way the subject lives noise. The modality we have observed most frequently (and the only *one* confirmed statistically) has been that whereby noise facilitates the slow depolarization of the cortex and CNV consequently increases in amplitude. Perhaps in this case the subject troubled by noise enhances his mental concentration while in the other group noise distracts the subject and so brings on a reduction in expectation and a consequently low amplitude CNV.

As we have already mentioned, this hypothesis fits in with the extreme diversity *from one* subject to another in the way in which noise is lived as an annoyance or, at times, as a pleasure (just think of habitués of pop music shows!).

eye or blinking movements thus being rejected The flash and click stimuli were distributed by a random stimuli programmer in the following sequence (trial) one flash (S_1) followed at 1100 msec by a series of clicks (S_2) at 10 c/sec, lasting 500 msec A random time of between 4 and 10 sec separated each trial A set of trials (flash + clicks) was first administered to eliminate the orientation reflex and create a condition of habituation to the stimuli the subject was then ordered to use the switch by his right hand in order to interrupt the series of clicks following the flash The CNV was obtained by summing 25 trial presentations and was recorded on paper by an X Y Moseley Plotter

RESULTS

The CNV's recorded in 12 subjects in condi tions of normal quiet background and during RN were considered The morphology duration and amplitude of each CNV were assessed No CNV duration modifications were observed in the two different experimental situations, only morphology modifications arising out of varia tions in amplitude which was measured at the point of maximum negative deflexion with respect to the baseline (Table 1)

In our research amplitude data are lower than those given in the literature because our computer unlike others utilized up to the present provides arithmetic means of each phenomenon and not sums of means. Although no modification was ever observed in the duration and form of the CNV s recorded with a normal quiet background and during RN amplitude

Table 1 *Amplitude in μV of the CNV recorded during a normal quiet background and during the administration of road noise (RN) Statistical significance data are shown for groups A and B The difference between the CNV amplitudes in the three groups considered overall was not statistically significant ($P < 0.30$)*

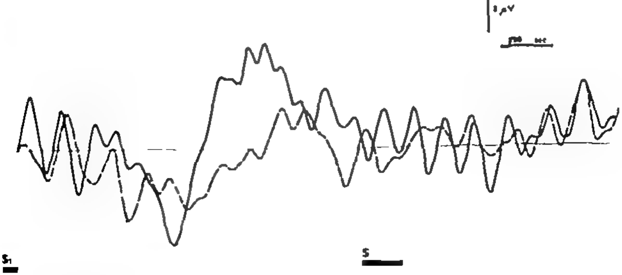

Fig 1 CNV (averaging of 25 responses) obtained in the same subject during normal quiet background (continuous line) and during RN administration (interrupted line) Note the greater amplitude of the CNV recorded during normal quiet background.

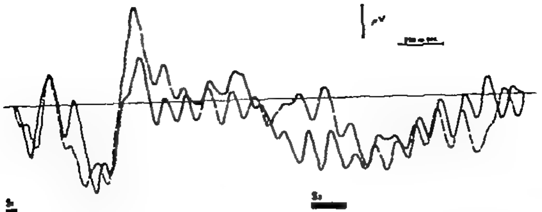

Fig. 2. CNV (averaging of 25 responses) obtained in the same subject during normal quiet background (continuous line) and during RN administration (interrupted line). Note the greater amplitude of the CNV recorded during RN

variations were not uniform. One group (A, Table 1) presented a fall in CNV amplitude during RN (fig. 1), another group (B, Table 1) an increase (fig. 2), while in two cases (C, Table 1), no modifications were observed at all.

It goes without saying that statistical analysis of the variation in CNV amplitudes of the group as a whole did not show any significance ($P < 0.30$). Nor was the CNV amplitude fall observed in four subjects (group A, Table 1) during administration of a quiet background statistically significant ($P < 0.10$). Only in group B of Table 1 (a group in which CNV presented increased amplitude during RN administration) was there any statistical significance ($P < 0.01$).

CONCLUSIONS

The findings show clearly that RN acts differently on the psychoattentive functions of the various subjects.

Moreover it is well known that the subjective sensation of "unpleasantness irritation" induced by noise does not arise at any specific intensity level but within ranges depending on the subject (between 40 and 90 dB according to Kryter 1970). The intragroup variability of CNV amplitude as observed by us confirms the above. But it is even more interesting to note that in a certain number of subjects CNV amplitude falls and in others it increases, as if to suggest that in the former RN irritates the psychoattentive processes set in motion by CNV while in the latter it facilitates them. Clearly the reason for this difference must be sought in the way in which noise triggers basic psychological mechanisms, in other words, in the way the subject lives noise. The modality we have observed most frequently (and the only one confirmed statistically) has been that whereby noise facilitates the slow depolarization of the cortex and CNV consequently increases in amplitude. Perhaps in this case the subject troubled by noise enhances his mental concentration while in the other group noise distracts the subject and so brings on a reduction in expectation and a consequently low amplitude CNV.

As we have already mentioned, this hypothesis fits in with the extreme diversity from one subject to another in the way in which noise is lived as an annoyance or at times, as a pleasure (just think of habitués of pop music shows!).

EEG CHANGES INDUCED BY EXPOSURE TO URBAN TRAFFIC NOISE AND WHITE NOISE

B Bergamasco P Benna, A M Covacich M Gilli

From the Department of Audiology and the Nervous and Mental Diseases Clinic University of Turin, Turin, Italy

SCOPE OF THE RESEARCH

Previous personal work had disclosed a marked reduction of acoustic response but unchanged visual response on the part of the cortex following exposure to traffic noise An interpretation for this pattern of cortical responsivity was sought by examining the EEG changes induced by the administration of road noise (RN) and white noise (WN) respectively

MATERIAL AND METHODS

A tape consisting of ten 1 minute recordings of daytime RN each taken at different points of Turin was used Its characteristics were

L_m dB	L_{eq} dB	$\sigma +$ dB
88 8	89 4	2.35
L_m dB(A)	L_{eq} dB(A)	$\sigma +$ dB(A)
71 6	73 1	3 54

This noise was fed through a Uher 4400 stereo I C recorder into the circuit of an Elit 815 audiometer and then passed to the subject via two loudspeakers placed 50 cm to the left and right of his head An evaluation of RN attenuated by 20 dB SPL was made at the point occupied by the head using a Brüel & Kjaer phonometer 2209 with a model 1613 octave filter WN was supplied at 85 dB SPL by the same audiometer

RESULTS

The most interesting finding (Table I) was the virtual absence of EEG desynchronization produced by both RN and WN in 9 subjects of the group of 10 subjects considered Desynchronization was indeed noted but for brief repeated periods (max 6-10") throughout exposure Surprisingly at the start of exposure it was very brief (2 3") and there was no "orientation reaction" It was also seen that desynchronization caused by WN was always much less, in spite of its greater intensity One subject, however displayed marked and lasting desynchronization on exposure to each type of noise This fact, coupled with the observation that desynchronization due to mental calculation in silence and on exposure to RN ad WN differed in all 10 subjects suggested that a Rorschach test should be run to see whether personality differences were affecting the EEG response to noise

A relation was found between basic affective components of personality and noise-induced EEG desynchronization as well as that induced by mental calculation in silence and on exposure to noise (fig 1 and 2).

CONCLUSIONS

The following conclusions can be drawn with respect to the effect of noise on the CNS noise leads to a reduction in cortical responsivity with respect to sensoriality related to sound itself and not to other sensorial stimuli in other words reduction of the potential elicited as the acoustic response and no effect on the visual response (see previous paper but one) RN and

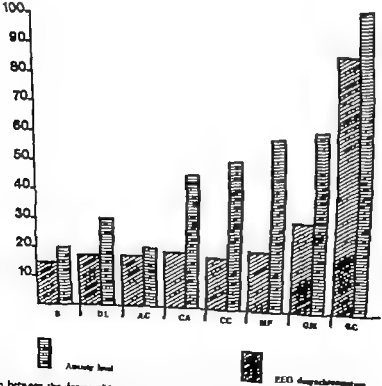

Fig. 1 Relation between the degree of Intimate dissonance of affection (IDA), as show by the Rorschach test, and percent of desynchronization induced by RN. The association between these parameters is particularly marked in subjects B. P. D. L. and A. C. (reduced IDA and the lowest desynchronization %) and in subject G. C. (very high IDA and highest desynchronization %). The remaining cases display similar proportionality

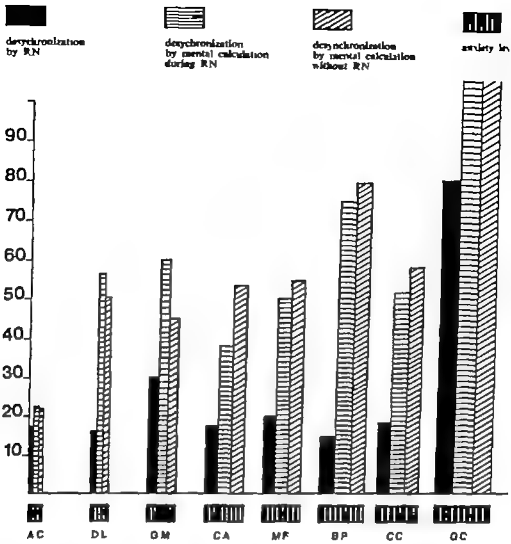

Fig 2 Relation between EEG desynchronization induced by RN and by mental calculation (with and without RN) and individual mental anxiety (Rorschach test). Anxiety is highest in cases where desynchronization caused by mental calculation during RN is less than during response. This suggests that RN acts as a "tranquilliser" of anxiety in subjects whith a high anxiety level, with the result that the calculation itself causes less desynchronization

WN result in no more than slight EEG desynchronization (and hence activation of the diffuse projection system) No "orientation reaction" is noted and there is no habituation A clear relation can also be discerned between the subject's overall affective component and his degree of desynchronization in response to noise and mental calculation Noise, in fact, can endured in a variety of ways. On the other hand these relations are not apparent in the changes of cortical responsivity to sensorial stimuli.

As matters now stand no satisfactory neurophysiological interpretation can be offered for these findings.

HUMAN SLEEP MODIFICATIONS INDUCED BY URBAN TRAFFIC NOISE

B Bergamasco, P Benna, M Gilli

From the Department of Audiology and the Nervous and Mental Diseases Clinic University of Turin, Turin, Italy

SCOPE OF THE RESEARCH

In previous research, we examined the effects of noise on various cerebral electrophysiological parameters with the encephalon in waking state. As it is widely believed that noise is the major sleep-disturbance factor we undertook a study of the modifications induced by road noise on human EEG during sleep road noise being an element of stress which is becoming more and more important, especially in large towns.

The literature, however contains few reports by workers who have studied the way in which noise interferes in this highly important factor in human homoeostasis. On the one hand, Kryter (1970) has highlighted the importance of certain noise characteristics (its intensity its unexpectedness, or the fact that it belongs to the subject s normal habitat, its continuity in time or the intermittence of its source) on the other Alexandre (1972 a, b) has demonstrated the importance of inherent factors within each individual These vary with the stage of sleep and the subject s age, sex, character and state of health. It is equally true, however that to some extent the subject manages to adapt to greater or less noise in his environment Schieber et al (1968) have shown that the depth of sleep falls proportionally to the background noise against which the subject sleeps. It has also been noted that the more an organism is in need of sleep, the higher becomes its threshold to noise stimuli This, however does not belie the current belief that noise disturbs a person tryi g to sleep

MATERIAL AND METHODS

Our research into the effects of road noise on sleep was carried out with the assistance of five normal volunteers of both sexes and aged between 23 and 32.

The road noise employed consisted of 3 recordings of night-time traffic made in 3 different points of Turin lasting 15 min each with intervals of 15 min silence. These were put on to 4 tapes of 90 min each to enable us to carry out experiments lasting 6 hours.

The road noise data in terms of L_m and L_{eq} were as follows

[illegible]	[illegible]	L dB	L_{eq} dB	dB	L_m dB(A)	L_{eq} dB(A)	+ dB(A)
1	0-15	63.3	65.6	1.7	53.7	54.7	1.6
2	15-30	87.7	89.3	4.1	74.9	76.9	4.3
3	30-45	63.4	[illegible]	1.6	54	54	0.6
4	45-60	86.5	[illegible]	4.62	71.6	74	4.2
5	60-75	63.9	64.2	1.65	54.2	54.2	0.86
6	75-90	87.9	90.7	4.5	73.4	77.7	4.43

The road noise was used with real intensity characteristics valued by means of a Brüel and Kjaer mod. 2209 phonometer with mod. 1613 octave filter at the subject s head

The tape was played on a Uher 4400 Report Stereo I C tape-recorder and put throug an Elit 815 audiometer into a free field from a speaker located half a metre from the subject s head. The subject was laid on a normal bed in a darkened room of the EEG section of the Clinic of Nervous and Mental Diseases, University of Turin.

Table 1 *Percentage values of the duration of the various stages of sleep in 5 normal subjects during administration of road noise compared with the average duration values of sleep phases in the normal adult*

Subjects	Aw	1.st St.	2.nd St	3.rd St	4.th St	REM St.
Sleep mean values in normal adult subjects	1	6	48	7	15	23
G P 23 y	7.8	11.5	35.8	6.5	9.8	29.6
M.A 26 y	2	9.3	59.8	16.9	0.9	11.1
R.G 46 y	10.6	11.6	33.7	10.8	5.7	27.6
C.F 32 y	21.5	14.6	38.8	16.9	8.2	0
C.P 30 y	3.5	12.9	51.6	7.9	6.2	17.9

Each subject began with a night of sleep during which noise was administered in the manner indicated in order to obviate those psychological problems which classically disturb the sleep of the normal adult (change of bed environment, background noise) The following night, EEG ECG and EOG were recorded using needle electrodes to permit subjects some motility during sleep

Before examining the results, it should be borne in mind that we did not compare sleep morphology during noise with the normal sleep morphology of the same subjects but with average statistical data in spite of the fact that each individual has his own sleep modalities.

This is because it was our intention to highlight the acute effects of noise with respect to an ideal functional situation Nor did we investigate the adaptation modalities of the nervous system obliged to sleep in a noisy environment

RESULTS

The results showed quantitative and qualitative alterations to sleep (Table 1)

First of all the arousal phase (including the waking period prior to going off to sleep as well as arousals during the night) was of greater duration percentage wise than normal values, obviously meaning a reduction in total sleep duration in its various stages.

The sleeping phase was much longer in all subjects, as may be seen in the percentage data relating to stage I although this, as already

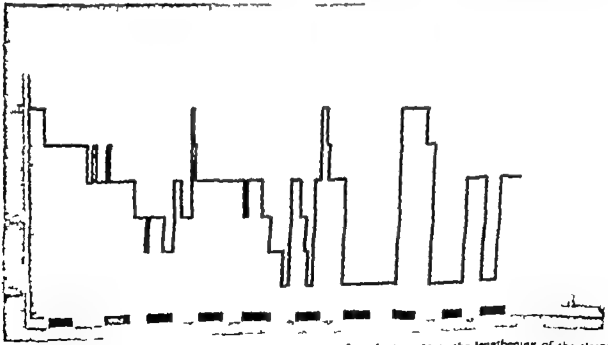

Fig 1 Hypnogram of a normal subject during administration of road noise Not the lengthening of the sleeping stage Hypnogram substantially preserved. (*white* silence black noise).

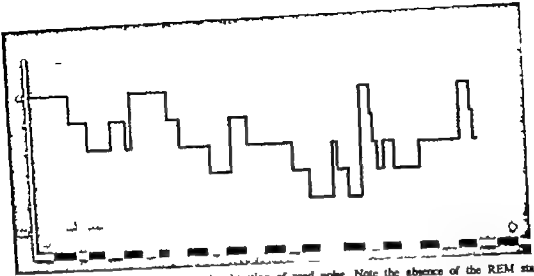

Fig. 2. Hypnogram of subject during administration of road noise. Note the absence of the REM stage. (white = silence, black = noise).

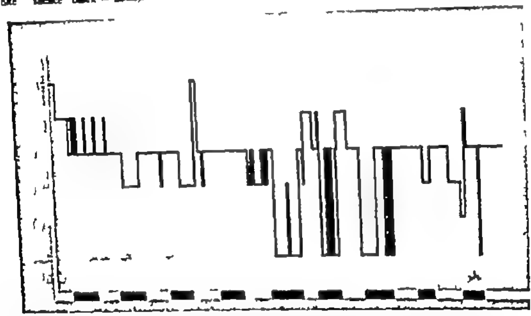

Fig. 3. Hypnogram of subject during administration of road noise. Note frequent periods of light sleep and the short duration of REM and IV stages. (white = silence, black = noise)

mentioned, takes in the numerous episodes of light sleep that occurred during the night. The duration of stage II was substantially the same while that of stage III was slightly increased, logically enough (this is the stage during which the "K complexes" occur, namely those bioelectric cortical potentials that would appear to be evoked by somatoaesthetic sensations and by external stimuli related to the state of marked neuronal hyperexcitability encountered in this stage of sleep). Alterations observed in stage IV were more marked (this is the stage of deep sleep during which the cortex produces large slow waves and loses its ability to respond to internal and external stimulation): the duration of stage IV was markedly reduced in all cases. The finding is of notable importance because this sleep stage is indispensable for CNS recuperation, like REM sleep, as is shown by sleep deprivation data (West, 1967).

The length of REM sleep was not substantially changed compared to average values in three of our cases in one case, the percentage of REM sleep was of short duration while another subject had no REM sleep at all. These latter two subjects enjoyed short percentage periods of IV sleep and high percentage periods of arousal (figs. 1 2, 3) It should be pointed out at this point that prior to EEG our subjects were put through personality tests and those presenting the most marked REM stage changes were found by these tests to be of "anxiety introversion" type

Although not disconnected with the subject's basic personality characteristics, these results still point to the gravity of the "noise-sleep disturbance" problem when it is considered that in our experimental situation, the night time noise administered was that of "normal" roads at various points in Turin

CONCLUSIONS

Our conclusions indicate that noise is a disturbing factor for the most delicate and demanding functions of the CNS in a high percentage of subjects and modifies the normal state of vigilance and particularly the regularity of sleep With the present techiques, this may be observed objectively in those "normal" subjects who present some instability in emotion control mechanisms We believe that in subjects where such control is disturbed (neurotics for instance) the effects are much more manifest and harmful and it is also likely that in such subjects noise plays a part in the development of mental disease symptomatology

EFFECTS OF URBAN TRAFFIC NOISE IN RELATION TO BASIC PERSONALITY

B Bergamasco, P Benna, P Furlan, M Gilli

From the Department of Audiology and the Nervous and Mental Diseases Clinic, University f Turin, Turin, Italy

Previous studies of cortical responsiveness to sensorial stimuli during the administration of Road Noise (RN) has offered uniform, statistically significant data only in the case of certain parameters such as Evoked Acoustic Potential (EAP) and Evoked Visual Potential (EVP). The other neurophysiological data (EEG desynchronization percentage and Contingent Negative Variation CNV) obtained with a normal quiet background and during the administration of RN have not on the whole shown any statistically significant difference The only possibility for interpreting the data was to establish, by investigating basic personality at what level of mental structure (and possibly in what way) noise acts.

We therefore put 12 subjects through the Rorschach test. Of all the parameters available, we obviously preferred those touching on affectivity namely "deep affective discordance" and "anguish" meaning by the former a central mental process and by the latter a more peripheral process close to the receiving organ (cortical stratum of Freud's ego) of sensory perceptions and mental reaction admission. In this way the mental sphere which is at one and the same time the site of the personality's deepest drives and feelings, may mediate between perception (centripetal) and reaction (centrifugal), although the reactions arising out of this sphere are blinder and less well controlled. By the term "anguish" we mean the strength of the defences, the strength of the ego or "extra tensional anguish" in Rorschach *terminology*

We are well aware that it is methodologically wrong to correlate parameters which are on scientifically different levels but a personality structure, or the depth of anguish, cannot yet be quantified electrophysiologically hence our desire to quantify the two basic parameters of the Rorschach test. By using such an approach, we were able to isolate two classes of subjects and obtain statistically significant electrophysiological data.

In a first group (Table 1 Group A) no difference was noted in the amplitude of CNV in relation to normal quiet background and RN while the greater percentage of EEG desynchronization during RN was highly significant. The investigation based on Rorschach's test showed shallow affective discordance and a high level of anguish.

In a second group of cases (Table 1 Group B) a statistically significant increase in CNV amplitude was encountered during noise, while the EEG desynchronization percentage was not statistically different during normal quiet background and RN In these cases, Rorschach's test highlighted deep affective discordance and a medium-to-low level of anguish. In such subjects, noise takes the place of the intratensional disturbing situation within the perceptive sphere thus facilitating the process of awaiting an event (and hence the CNV) and reducing EEG desynchronization.

Finally in a third group (Table 1 Group C), previous findings were confirmed. There were no substantial differences in CNV amplitude

Table 1 *Effects of urban traffic noise in relation to basic personality*

Group	Subjects	CNV during psychosensory rest. Amplitude in µV	CNV during RN Amplitude in µV	% EEG desynchronization during psychosensory rest	% EEG desynchronization during RN	Rorschach's test. Deep affective dissonance	Rorschach's test. Anguish's level

		P = N.S		P = N.S.			

and the EEG desynchronization percentage in the two experimental situations (normal quiet background and RN) But owing to the particularly complex structures of personalities in this group Rorschach's test did not throw up any unquestionable significance in the two chosen parameters. The results thus confirm the fundamental importance of basic personality in the way noise is lived and its greater or smaller capacity to disturb

MEASUREMENT OF PHONATORY LEVEL IN THE PRESENCE OF URBAN TRAFFIC NOISE

O Schindler M. Vigono

From the Department of Audiology University of Turin, Turin, Italy

SCOPE OF THE RESEARCH

Modifications in the laryngeal or more broadly verbal effector as a response to the presence of a pre-established environmental noise (road noise) have been examined with a view to creating a more favourable signal/noise relation in verboacoustic communication.

MATERIAL AND METHODS

The examination procedure involved having a prose passage read by subjects in a quiet room, the phonatory level was measured by means of a Brüel & Kjær mod. 2209 phonometer with mod. 1613 octave filter (scale dB A) placed 5 cm from the mouth (and nose). Sound pressure level was recorded by means of a Brüel & Kjaer mod. 2305 recorder and data were subsequently processed.

The same measurements were then repeated during administration into both earphones of road traffic noise with real intensity characteristics.

The noise recorded on the tape consisted of ten recordings of one minute each carried out at ten different points of Turin during daytime

The following road noise data, in terms of L_m and L_{eq} were adopted

L_m dB	L_{eq} dB	σ + dB
88.8	89 4	2.35
L_m dB(A)	L_{eq} dB(A)	σ + dB(A)
71.6	73 1	3.54

The tape was played on a Uher 4400 Stereo Report I C recorder and transmitted to an Amplaid 500 audiometer calibrated in SPL.

Female subjects aged between 18 and 21 free from organic and functional phonoarticular defects, were chosen.

RESULTS

The experiments were confined to 5 + 5 in view of the homogeneity of the subjects and the small standard deviation (2 σ).

Results are shown in Table 1 fig. 1 shows an example of one of the charts obtained during the experiment.

Table 1 *Equivalent phonatory levels obtained without and with road noise*

Subjects	dB (A) without noise	dB (A) with noise
R P	62.5	68.3
M.G.	64.5	75.5
B D	60 0	71.5
P.P	65 7	74.8
L.O	62.6	73.5
Average value	63 06 ± 2.18	72.72 ± 2.90

Values have been considered as an expression of phonatory level, namely as an expression of the level of laryngeal sound modified by the resonance cavities even though in fact they express the sum of the levels of phonemes produced prevalently at laryngeal level and of

Table 1 *Effects of urban traffic noise in relation to basic personality*

	Subjects	CNV during psychosensory rest. Amplitude in μV	CNV during RN Amplitude in μV	EEG desynchronization during psychosensory rest	% EEG desynchronization during RN	Rorschach's test. Deep affective dissonance	Anguish's level

INTELLIGIBILITY OF SPOKEN WORDS IN THE PRESENCE OF URBAN TRAFFIC NOISE

O Schindler M Vigone

From the Department of Audiology University of Turin, Turin, Italy

SCOPE OF THE RESEARCH

An investigation was made of quotients of intelligibility with various types of signal/noise (S/N) ratio, using traffic noise at its actually recorded intensity

MATERIAL AND METHODS

The experiment was designed for road traffic noise. For this purpose, a tape consisting of the 1-minute recordings of daytime road noise, each taken at different points of Turin, was used Its characteristics were

L_m dB	L_{eq} dB	$\sigma +$ dB
88.8	89.4	2.35
L_m dB(A)	L_{eq} dB(A)	$\sigma +$ dB(A)
71.6	73.1	3.54

This noise was fed through a Uher 4400 stereo I C recorder to an Amplaid 500 audiometer calibrated in dB SPL, and then on to a loudspeaker Output levels corresponding to the figures given above were measured 3 m from the loudspeaker with a Brüel & Kjaer 2209 phonometer fitted with a 1613 octave filter

At the same time, Bocca s lists of two-syllable words recorded on an Amplifon disk were mixed with the road noise through an Amplifon 300 G5 audiometer and the Amplifon 500 Levels recorded in dB SPL on the audiometer were checked as already described

10 females aged 19-21 yr and 4 adults aged 40-50 yr were used. Each subject was placed 3 m in front of the loudspeaker in a soundproof room and required to repeat the words be heard in accordance with the classic rules of vocal audiometry Three lists of 10 words each were employed for each level Intelligibility was assessed as the mean of the three percents.

RESULTS

Table 1 shows the means obtained for each subject and for each S/N level

Table 1 *Intelligibility quotient for various S/N ratios (mean of three tests per subject and per ratio).*

Sound Noise Ratio	Young Subjects (18-21 yrs.)										Adult Subjects (40-50 yrs.)			
	B R	Ro P	Ri P	B L	P.P	G G	P.E.	P.M.	G.D	G.B.D.	O G.C.	S O	B L	R.G

90 90	90	90	100	100	100	100	100	100	100	100	96	96	93	100
100 90	100	100	100	100	100	100	100	90	100	90	86	93	96	96

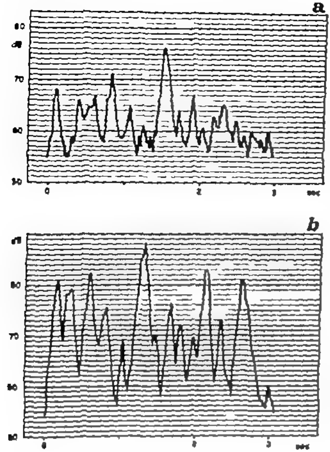

Fig 1 Graph of phonatory level without (a) and with (b) road noise.

the phonemes produced prevalently at articular level. This depends on the fact that the longer relative duration occurs in the former the approximate ratio with respect to the latter being 2 1

Further more than half the phonemes produced at prevalently articular level have decidedly lower levels than those produced prevalently at laryngeal level To conclude it can be broadly assumed that the levels of verbal expression are a function of laryngeal phonatory activity

CONCLUSIONS

The relative dimensions of the data would appear to be particularly significant as they indicate a difference of some 10 dB between the measurements without noise and those with

It should be pointed out that the experimental situation prevented autophony by the auricular airway which was impeded by the presence of the earphones It would perhaps have been useful, in absolute terms to take measurements in linear dB also remembering the considerable spectral component lower than 500 Hz. From a communications point of view (see the results of the sonographic research on phonemic emission) the component beneath 500 Hz is the least important because it is masked by environment noise, particularly road noise

In biological terms, an increase of about 10 dB in the level corresponds to a much greater force because it is measured in terms of energy not of psycho-acoustic measurement This greater effort can be chiefly identified in the lungs which have to guarantee a ten-fold increase in expiratory pressure In this regard, corresponding spirometric measurements would be of interest, even though such operations are rather complex. Laryngeal effort is also considerably increased but direct evaluation is difficult Allowance should also be made for the fact that the lungs are not always capable of assuring the above energy increases so the increase in phonatory emission level is often compensated for by greater effort on the part of the intrinsic and extrinsic laryngeal muscles.

Electromyography might also be used for checking these data

In terms of possible damage at the level of phonatory effectors, we must not forget other harmful non-auditory conditions represented by stress factors and, particularly by the atmospheric pollution typical of road conditions which electively affect all respiratory ways.

From the communications viewpoint, an average absolute value of the order of 70-75 dB (A) in verbalization conditions in the presence of road traffic noise clearly indicates, if compared with road traffic values, what types of signal/noise relationship occurs in these conditions and particularly how rarely phonatory level reaches road traffic levels. This last point is discussed separately in the paper on the intelligibility of verbal messages.

Young subject responses

As can be seen from the standard deviation, these varied very little. The index of intelligibility (81.30 %) for the S/N ratio 75/90, i.e. normal speech, in the presence of traffic noise was reasonably satisfactory, bearing in mind that two-syllable words were used. A considerable increase could undoubtedly be obtained with sentences or complete conversations (obviously at medium to high redundancy). Note should also be taken of the fact that the lists of words were spoken by a professional speaker at a less-than-normal speed. The index of intelligibility was 98 % at the S/N ratio 90/90 (speech and noise at the same level).

Adult subject responses

These were less uniform. However, the group consisted of a mere four persons and cannot be used as a basis of definite conclusions. Comparison between young and adult subjects, in fact, was not contemplated as part of the research aim, but was considered as a first check on the data obtained for the young subjects.

Nevertheless, the curve for the adult subjects was distinctly different from that for the young subjects (fig. 1). At 70 dB, the index of intelligibility was only 25.5 %, i.e. useless as far as comprehension was concerned. Satisfactory values were obtained from 75 dB onwards. There was also a flexion of quotients on passing from 90/90 to 100/90 S/N. Experimentation on a larger series and the carrying out of conventional tonal and vocal audiometric tests (including central vocal tests) can state as a first approximation that adult subjects already display deterioration of the central acoustic pathway capacity, particularly of the ability to achieve optimum understanding of a message.

CONCLUSIONS

Our results offer a reference point for the evaluation of

- the intelligibility of various types of natural voice. Account must be taken of the frequent aphonia, dysphonias and phonasthenias that prevent a satisfactory phonatory level from being achieved at 75 dB
- intelligibility at various S/N ratios for subjects of different ages
- intelligibility at various S/N ratios on the part of subjects with various diseases of the CNS in the light of the more frequent epidemiological data
- the use of means for the amplification of speech signals that reach and surpass the levels of traffic noise.

It should, of course, be realised that the experimental conditions employed did *not offer* a true picture of what really occurs, since each electro-acoustic transduction and each passage through an electronic system leads to changes in and restrictions of the spectra. Both qualitative and quantitative variations are produced in both the signal and the noise. Lastly, the overall atmosphere of communication is considerably affected by the reproduction of speech in a soundproof room. Discrepancies may also exist between the various systems and the measurement units for the acoustic levels.

Table 2. *Means and standard deviations (2 σ) of the intelligibility quotient values for the two groups (young and adult subjects).*

Sound/Noise Ratio	Young Subjects (18-21 yrs.) Mean Value	Adult Subjects (40-50 yrs.) Mean Value
65/90	18.80 ± 10.94	0.75 ± 1.50
70/90	55.50 ± 15.64	25.50 ± 14.27
75/90	81.30 ± 12.53	69.75 ± 10.07
80/90	92.70 ± 6.84	68.25 ± 15.88
90/90	98.00 ± 4.21	96.25 ± 2.87
100/90	98.00 ± 4.21	92.75 ± 4.71

Table 2 shows the means and standard deviation (2 σ) for the two groups of subjects.

Figure 1 gives the mean value curves for the two groups.

Figure 2 shows the response field for the young subjects as derived from the mean values and standard deviation.

Figure 3 shows this field for the adult subjects.

Two-syllable word levels were chosen to obtain values similar to those measured on speech with and without traffic noise in the preceding paper and to have S/N ratios equivalent to 0 and —10 and + 10 respectively

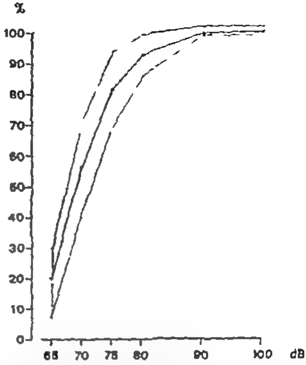

Fig 2 Percent intelligibility of lists of words (at different intensity levels) in the presence of road noise. Variability of response (dark band) on the basis of mean values and standard deviations (young subjects).

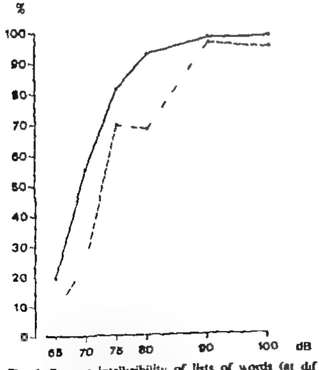

Fig 1 Percent intelligibility of lists of words (at different intensity levels) in the presence of road noise. Curves of mean values (——•—— *young subjects* – –•– adult subjects)

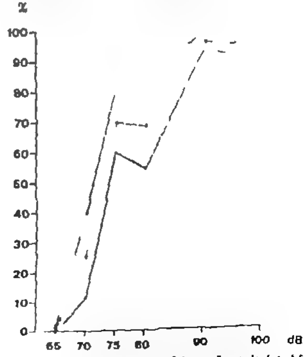

Fig 3 Percent intelligibility of lists of words (t different intensity levels) in the presence of road noise Variabil ty of response (dark band) on the basis of mean alues and t

Young subject responses

As can be seen from the standard deviation, these varied very little. The index of intelligibility (81.30 %) for the S/N ratio 75/90, i.e. normal speech, in the presence of traffic noise was reasonably satisfactory bearing in mind that two-syllable words were used. A considerable increase could undoubtedly be obtained with sentences or complete conversations (obviously at medium to high redundancy). Note should also be taken of the fact that the lists of words were spoken by a professional speaker at a less-than-normal speed. The index of intelligibility was 98 % at the S/N ratio 90/90 (speech and noise at the same level).

Adult subject responses

These were less uniform. However the group consisted of a mere four persons and cannot be used as a basis of definite conclusions. Comparison between young and adult subjects, in fact, was not contemplated as part of the research aim, but was considered as a first check on the data obtained for the young subjects.

Nevertheless, the curve for the adult subjects was distinctly different from that for the young subjects (fig. 1). At 70 dB the index of intelligibility was only 25.5 %, i.e. useless as far as comprehension was concerned. Satisfactory values were obtained from 75 dB onwards. There was also a flexion of quotients on passing from 90/90 to 100/90 S/N. Experimentation on a larger series and the carrying out of conventional tonal and vocal audiometric tests (including central vocal tests) can state as a first approximation that adult subjects already display deterioration of the central acoustic pathway capacity particularly of the ability to achieve optimum understanding of a message.

CONCLUSIONS

Our results offer a reference point for the evaluation of

— the intelligibility of various types of natural voice. Account must be taken of the frequent aphonia, dysphonias and phonasthenias that prevent a satisfactory phonatory level from being achieved at 75 dB
— intelligibility at various S/N ratios for subjects of different ages
— intelligibility at various S/N ratios on the part of subjects with various diseases of the CNS in the light of the more frequent epidemiological data
— the use of means for the amplification of speech signals that reach and surpass the levels of traffic noise.

It should, of course be realised that the experimental conditions employed did not offer a true picture of what really occurs, since each electro-acoustic transduction and each passage through an electronic system leads to changes in and restrictions of the spectra. Both qualitative and quantitative variations are produced in both the signal and the noise. Lastly the overall atmosphere of communication is considerably affected by the reproduction of speech in a soundproof room. Discrepancies may also exist between the various systems and the measurement units for the acoustic levels.

RESEARCH ON PHONEME EMISSION IN RELATION TO URBAN TRAFFIC NOISE

O Schindler

From the Department of Audiology University of Turin, Turin Italy

SCOPE OF THE RESEARCH

The purpose of the research is to evaluate the quality and quantity aspects of certain verboacoustic communication parameters in the presence of road traffic noise It is a well known fact that verboacoustic communication must take account of the perceptive integrative and executive sectors of the communicating partners as well as the characteristics of the channel between the partners

The overall problem involves a vast number of parameters (all inter related) and it is obviously out of the question to consider them all here We will also give brief mention to the relative catalogue using this also as an index of research approaches that should form part of a verboacoustic communication programme in a noisy environment The interest of this type of communication is of fundamental importance since for the moment and presumably for a long time to come the physiological state (meaning the statistical norm) of verboacoustic communication implies a very noisy background This is why for biologico-communicative economy purposes the parameters of verboacoustic messages certainly change to adapt to a much different situation from that pertaining during the long period that terminated only a few decades ago in which the quantity/quality of background noise fostered quite another system of verboacoustic communication

Perceptive sector parameters

Auditory evaluation of the various types and extents of pathology of the hearing system in relation to the translation and optimization of an acoustic message with a given S/N ratio.

Extra-auditory as communication is a global event, it is important to evaluate non-acoustic messages (particularly optical and vibratory other than chemical) in relation to their reinforcement or disturbing effect on the information channelled through the acoustic message It is therefore clear that the physiology and pathology of the non-auditory sensory sistems must be evaluated

Integrative sector parameters

It is evident that the above mentioned modifications in messages with respect to perceptive parameters are upset at integrative level and in view of the considerable rise in peripheral message total bit/sec which largely exceed the maximum processing capacity of the human communications system a new choice strategy is called for

We would undoubtedly attribute the message optimization phenomenon to the integrative sector also even though it still belongs to the perceptive sector (central sensory ways) At this point we must also examine message profile and its breakdown into various channels, each of which has its own signal/noise ratio

Here too we should evaluate the semiotic and semantic data relating to signal and noise so as to establish the redundancy of the message which in our opinion ought to be increased as a result of the data presented above with respect to the specifically verboacoustic aspect and globally as a result of reinforcement through the extra-acoustic channels

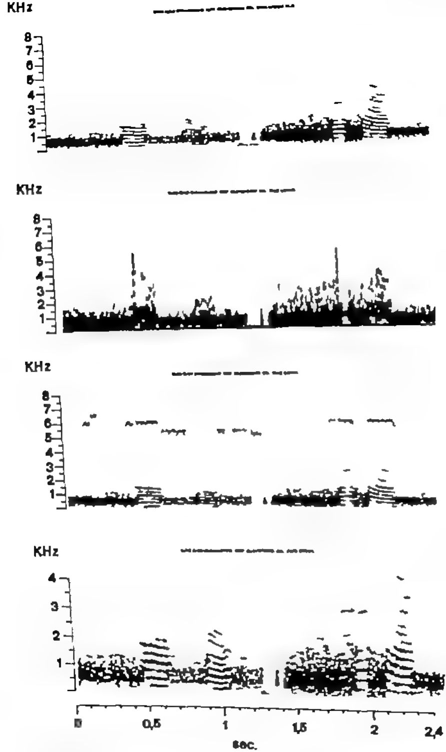

Fig. 1 (babbo papà) Excellent preservation of vowel structures as regards their parameters of fundamental frequency formants and transitories. Poor consonant reading. Specifically explosion noise is only heard on the first P of papà. The vocal bar of voiced occlusives not identifiable. Explosion peaks of B's easily identifiable on the level curves.

RESEARCH ON PHONEME EMISSION IN RELATION TO URBAN TRAFFIC NOISE

O Schindler

From the Department of Audiology University of Turin, Turin Italy

SCOPE OF THE RESEARCH

The purpose of the research is to evaluate the quality and quantity aspects of certain verbo-acoustic communication parameters in the presence of road traffic noise It is a well known fact that verboacoustic communication must take account of the perceptive integrative and executive sectors of the communicating partners as well as the characteristics of the channel between the partners

The overall problem involves a vast number of parameters (all inter related) and it is obviously out of the question to consider them all here We will also give brief mention to the relative catalogue, using this also as an index of research approaches that should form part of a verboacoustic communication programme in a noisy environment The interest of this type of communication is of fundamental importance since for the moment and presumably for a long time to come the "physiological state (meaning the statistical norm) of verboacoustic communication implies a very noisy background This is why for biologico-communicative economy purposes, the parameters of verboacoustic messages certainly change to adapt to a much different situation from that pertaining during the long period that terminated only a few decades ago in which the quantity/quality of background noise fostered quite another system of verboacoustic communication

Perceptive sector parameters

Auditory evaluation of the various types and extents of pathology of the hearing system in relation to the translation and optimizatio an acoustic message with a given S/N rati

Extra-auditory as communication is a gl event it is important to evaluate non-acou messages (particularly optical and vibrat other than chemical) in relation to their r forcement or disturbing effect on the informat channelled through the acoustic message. I therefore clear that the physiology and pathol of the non-auditory sensory sistems must evaluated

Integrative sector parameters

It is evident that the above mentioned modifi tions in messages with respect to perceptive pa meters are upset at integrative level and in vi of the considerable rise in peripheral mess total bit/sec which largely exceed the maxim processing capacity of the human communi tions system a new choice strategy is called f

We would undoubtedly attribute the messa optimization phenomenon to the integrati sector also even though it still belongs to t perceptive sector (central sensory ways) At th point we must also examine message profi and its breakdown into various channels ea of which has its own signal/noise ratio

Here too we should evaluate the semiot and semantic data relating to signal and noi so as to establish the redundancy of the messag which in our opinion, ought to be increase as a result of the data presented above wit respect to the specifically verboacoustic aspec and globally as a result of reinforcement throug the extra acoustic channel

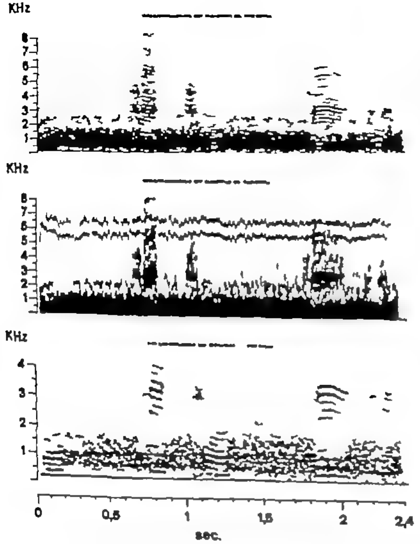

Fig 4 (accio gigi). Very good vowel phoneme preservation in all parameters. Considerable deterioration of consonant phonemes of which only the constrictive component (including vocal bars is legible) while the occlusiv component is quite illegible.

Executive sector parameters

Again, at message production level, we shall ha e to evaluate the communications profils in at least three main sectors

— erbal
graphico-pictorial
— mimico-gestural

Substantially we are in the presence at verbal level of an attempt to offset an unfavourable S N ratio by ncreasing phonatory level. As this has evident upper limits (see also the results of the other two *researches in* this group), other compensating factors at executive level inevitably are triggered over and above the redundancy compensations that do not belong to this sector and in addition *to the* modifications (slowdown) in verbal flow

Emotive-relational sector parameters

It is a well-known fact *that* as communication is a social phenomenon it depends *on* the choice of a common code between the partners, on the learning of this code (developmental biology) and on the emotive-relational state of the communicating group and its components.

Interindividual channel parameters

This concerns evaluations of the external environment in relation to all types of communi-

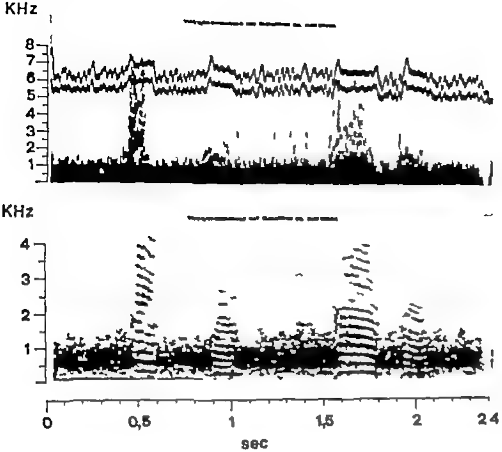

Fig 2 (tetto dado) The various parameters of the vowel structures well preserved. Greater deterioration of consonant structures. Explosion noise detected in all cases (including on the level curves). A hint of vocalic bar on the second D of dado

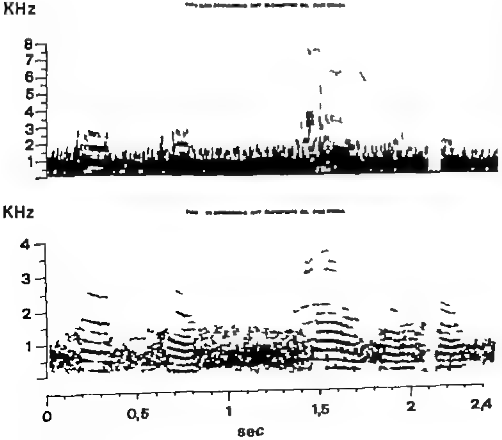

Fig 3 (cocco lago). Vowel structures well preserved in all parameters. Greater deterioration of consonant structures. Explosion noise in two out of three cases. Explosion peak present in the three cases. Vocal bar hard to pick out on the G

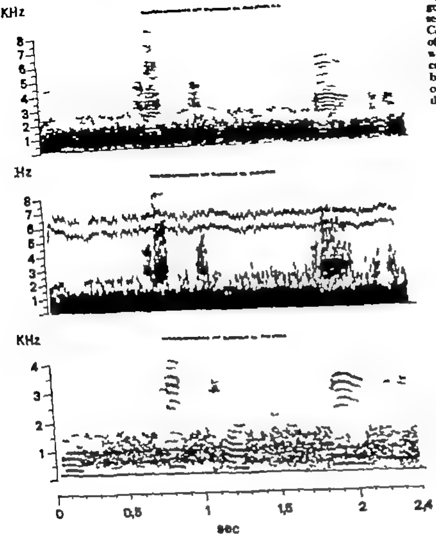

Fig. 4 (decoo gigi). Very good vowel phoneme preservation in all parameters. Considerable deterioration of consonant phonemes of which only the constrictive component (including ocal bars is legible) while the occlusive component is quite illegible.

Executive sector parameters

Again, at message production level, we shall have to evaluate the communications profils in at least three main sectors

— verbal
— graphico-pictorial
— mimico-gestural.

Substantially we are in the presence at verbal level of an attempt to offset an unfavourable S/N ratio by increasing phonatory level. As this has evident upper limits (see also the results of the other two researches in this group), other compensating factors at executive level inevitably are triggered over and above the redundancy compensations that do not belong to this sector and in addition to the modifications (slowdown) in verbal flow

Emotive-relational sector parameters

It is a well-known fact that as communication is a social phenomenon it depends on the choice of a common code between the partners, on the learning of this code (developmental biology) and on the emotive-relational state of the communicating group and its components.

Interindividual channel parameters

This concerns evaluations of the external environment in relation *to all* types of communi-

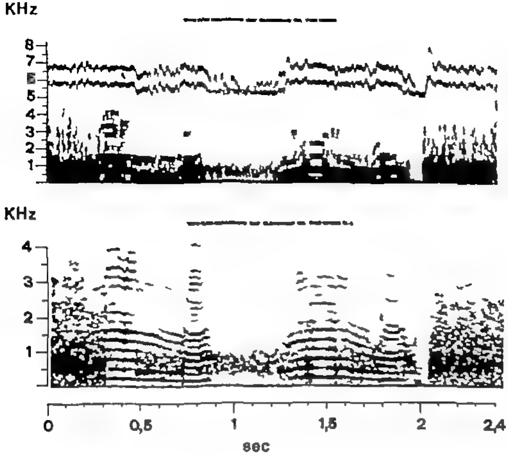

Fig 5 (mamma nonna). Good preservation of vowel phonemes in all parameters. Consonant phonemes also well preserved, particularly the harmonic structure of nasal resonance (more evident on the N's than on the M's). Explosion noises not evident on the M's, but evident on the N's.

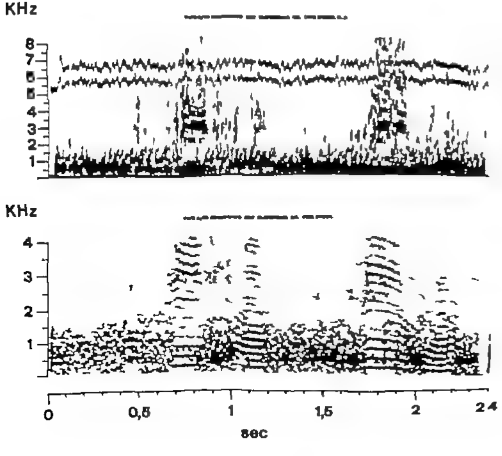

Fig 6 (fifa vi a). Good preservation of vowel phonemes in all parameters. Very bad preservation of consonant phonemes which are partially confused with traffic noise. The harmonic sonanization components of the V almost illegible. The harmonic structure preceding FIFA is made by a car horn.

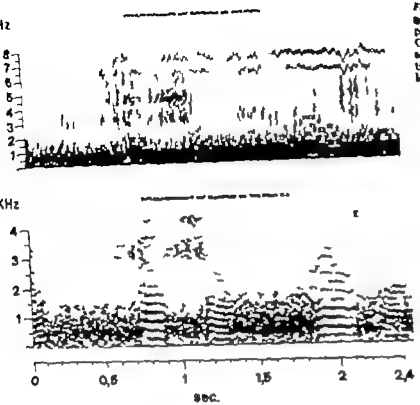

Fig 7 (sasso rosa). Very good preservation of vowel phonemes in all parameters. Good preservation of consonant phonemes. Sonorization of the S in rosa not legible.

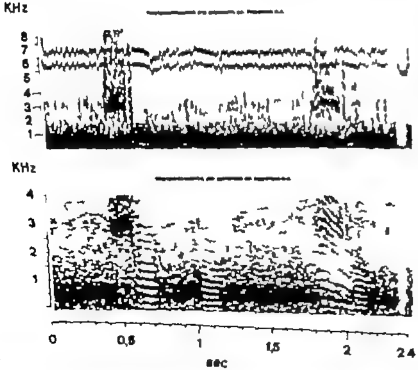

Fig 8 (scirocco zia). Very good preservation of vowel phonemes in all parameters. Very good preservation of SC phoneme parameters. Poor preservations of phoneme Z parameters and it is hard to distinguish any constrictive component structure.

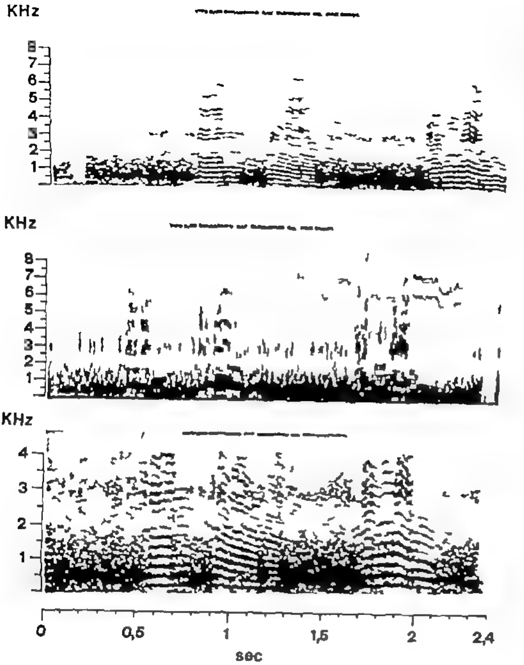

Fig 9 (zanzara lulu). Very good preservation of the vowel structures in all parameters. *Very bad* preservation of the Z structures apart from some sonorization. Good preservation of L structures.

cation It is important to stress that allowance should also be made insofar as they are component parts of the outside environment, of the means and instruments used for indirect communication (prostheses of various types, mass media, etc)

MATERIAL AND METHODS

This section covers a qualitative-quantitative but prevalently qualitative electroacoustic analysis of phoneme material produced directly in road traffic. A young woman trained to articulate *clearly* (she is a logopaedist) was made to repeat a list of words in a street where traffic noise was considerable The list of words corresponds to that normally used at our Department for the analysis of phonemes produced by logopathic patients Here it is

papà babbo tetto dado cocco lago
ciccio gigi mamma nonna fifa viva
sasso rosa sciocco zia zanzara lulu
ramarro rana giugno luglio strada
spruzzo taxi

It comprises all phonemes in the Italian language in the body of words. Although the various items have a semantic content classing

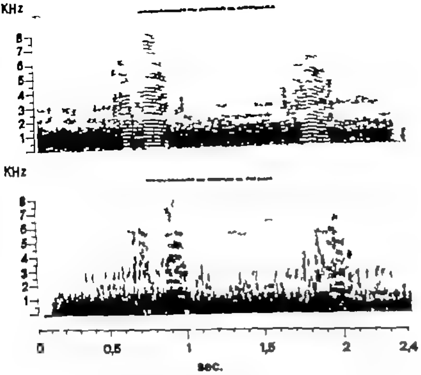

Fig 10 (ramarro rana). Very good preservation of vowel structures with respect to all parameters. Good preservation of R structures.

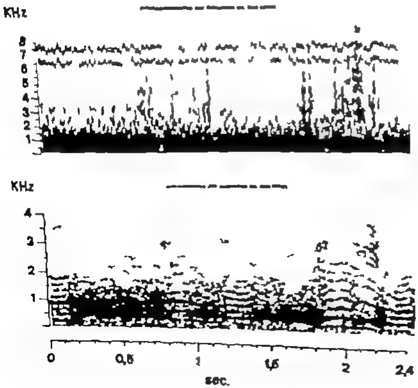

Fig 11 (giugno luglio). Very good preservation of vowel structures in all parameters. GN structure preservation not good better but still not good the GL structures.

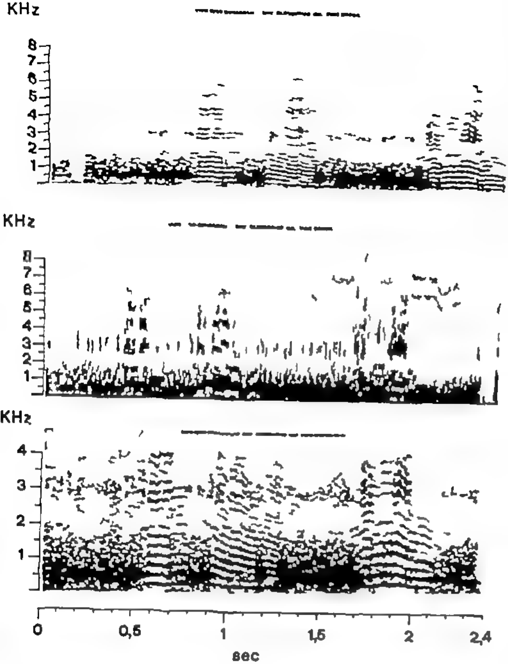

Fig 9 (zanzara lulu) Very good preservation of the vowel structures in all parameters. Very bad preservation of the Z structures apart from some sonorization. Good preservation of L structures.

cation It is important to stress that allowance should also be made, insofar as they are component parts of the outside environment of the means and instruments used for indirect communication (prostheses of various types, mass media etc)

It comprises all phonemes in the Italian language in the body of words. Although the various items have a semantic content classing

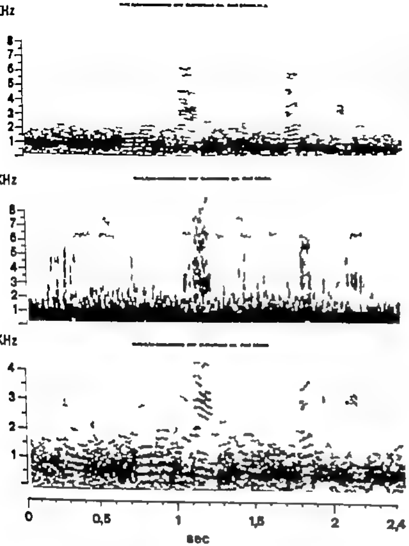

Fig 13 (completo taxl) Very good preservation of vowel structures in all parameters. Preservation of MPL group structures not good although the M and L components are legible. Structures of the CS group very badly preserved (including the constrictive component).

3) Wide band analysis with frequency spectrum from 80 to 8000 Hz

4) Analysis of level curves (normal and —10 dB) level curves are always compared with narrow and wide band analyses with frequency spectrum from 80 to 8000 Hz.

RESULTS

Result of the nalyses are shown in the captions f om figs. 1 13 Synthesizing the results, the following remarks can be made

— The road traffic noise spectrum disturbs the reading of phonemes a great deal up to 1000 Hz disturbance is decidedly less from 1000 to 2000 Hz and practically nonexistent from 2000 to 8000 Hz. It should also be borne in mind that at auditory level, the disturbance tends to shift towards acute frequencies by reason of the masking effect of low pitched frequencies.

— The level, frequency and spectrum suprasegmentary gross dynamics, in other words the rhythmic structures of the phrase are sufficiently well preserved. A marked slowdown in verbal flow i.e. in the number of phonemes per unit of time, should be noted. This occurs prevalently by way of the lengthening of vowel phonemes and constrictive conso-

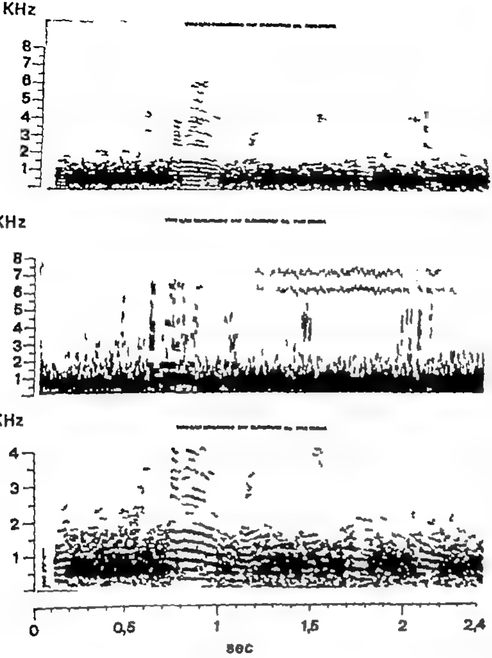

Fig 1 (strada spruzzo). Very good preservation of vowel structures in all parameters. Poor preservation of STR and SPR group structures best preservation seen in constrictive and liquid component

them as physiological rather than artificial they can be considered in practically the same way as logatomes given their brevity and the fact that they are not connected within a sentence

The chosen road was via Genova running alongside Turin's General Hospital (Molinette Section). This is a road of average width (about four cars side by side) used by public (including trams) and private traffic. It is flanked both sides by buildings, the distance between them being about three times the width of the carriageway

Measurements were taken at 11 a. m. when traffic flow is at its average day time level. The noise level and spectra were on a par with those used on tapes in the other two researches. In view of the prevalently qualitative character of the study we did not consider it necessary to investigate the quality-quantity aspects of road traffic noise at the point in question

The repeated words were recorded on a Uher 4400 Stereo Report I C recorder and then analysed electroacoustically with the Sonograph Kay

The following types of analysis were undertaken

1) Narrow band analysis with frequency spectrum from 80 to 8000 Hz
2) Narrow band analysis with frequency spectrum from 80 to 4000 Hz

URBAN TRAFFIC NOISE, CARDIOCIRCULATORY ACTIVITY AND CORONARY RISK FACTORS

L. Verdun di Cantogno R. Dallerba, P.S. Teagno, L. Cocola

From the Department of Audiology and the 1st Department of Medical Patology University of Turin, Turin, Italy

SCOPE OF THE RESEARCH

The aim of this research was an assessment of the effect of road noise lasting 10' on cardiocirculatory activity and various blood chemistry indices, particularly those apparently associated with the pathogenesis of arteriosclerosis. Normal, dysmetabolic and coronaropathic subjects were examined.

While it can readily be appreciated that certain stimuli can act on the cardiovascular apparatus, leading to changes in the work of the heart and its performances, it is less easy to understand how certain psychological and emotional conditions, or certain sensorial stimuli completely mediated by the CNS influence the heart and its vessels, thus supporting atheroma, endoarterial thrombosis or serious arrhythmias.

Acoustic stimuli offer an ideal method for the study of effects mediated by the CNS, since they can be exactly reproduced and measured in the absence of every other factor likely to influence cardiac frequency and arterial pressure, or left ventricular performance as assessed by simultaneous ECG phonocardiographic and carotid pulse recordings. Attention was also given to the blood chemistry indices known as related to coronary risk factors. Direct evaluation of catecholamine levels was not attempted, because this technique gives widely scattered results, even under normal conditions. Urinary catecholamines excreted during the test were however taken into consideration. The limitations of this method are well known.

MATERIAL AND METHODS

The absence of literature data concerning the effect of traffic noise on the parameters chosen for study suggested the advisability of preceding the experiment by a series of investigations of the effect of white noise and speech noise (100 dB and 80 dB intensity continuous stimulation for 10' or for 1' followed by an interrupted stimulation for 9') in 16 subjects, *to determine the* effect *of* noise of different spectrum and intensity administered with different modalities. This preliminary study (details in the press) showed statistically significant differences between stimulated and control subjects. We therefore began by exposing 33 subjects aged 20-70 yr to road noise. A further 11 normal subjects (mean age 27 yr) were studied for comparison, i.e. they were subjected to all the experimental procedures in the absence of road noise (control group).

Prior audiometric examination showed that all subjects had normal hearing for age. Only male subjects were examined, so as to ensure that responses were not affected by neurohormonal and neurophsychic factors pertinent to the two sexes.

The patients were divided into 3 groups (11 normals, average age 36.7 yr 11 diabetic or dyslipaemic, average age 46.4 yr 11 coronaropathic, average age 52 yr). As already stated, the average age of the 11 controls was 27 yr A division was also drawn between subjects aged more and less than 45 yr., i.e. 17 (mean

nant phonemes as it is evident that occlusive consonant phonemes cannot be lengthened These data implicity lead to some rhythm modification
— Vowel structures are well preserved with respect to all vowel phonemes and all their parameters (harmonic, melodic dynamic structure, formant and transitory structures) It should however be recalled that these remarks apply if laryngeal function is good, for if laryngeal emission is affected by pathological factors, the sound structure is transformed partially or wholly into a noise structure and the readability of vowel phonemes deteriorates drastically
— Occlusive consonant structures (P B M T D N K Gh Gn) are badly deteriorated

The following parameters are considered in particular
— pre-explosion quiet deteriorated because it is filled with traffic noise which also wipes out sonorization of sonant orals (there is practically no vocal bar) By contrast, sonorization of nasals (with the sole exception of Gn) is well preserved
— explosion noise detectable as such in a differentiated way

very poor for bilabials
good for linguoalveolodentals
fair for dorsivelars.

A similar situation although more favourable is evident reading level curve peaks.
— Formant transitories with preceding and following vowels satisfactory in all cases less satisfactory with the first formant and more the higher the frequency of the second formant In conclusion reading of these consonants may be summarised in the following table

poor P B K Gh
average Gn T D
good M N

— Constrictive consonant structures (F V S S Sc, Gl L, R) are adequately preserved on the whole

Liquids and vibrants are best preserved (providing they are not in the body of consonant groups). The following remarks can be made about the remaining constrictives
— Formant areas are clearly readable as regards phonemes S Ş and Sc, and very poorly readable as regards F and V
— V and Ş sonorization is badly deteriorated

To conclude reading of these consonants may be summarized in the following table

poor F V
average S
good L, R Gl Ş Sc

— Semiconstrictive consonant structures (Z, Z, $C_{()}$ $G_{()}$ are all badly deteriorated particularly as regards their respective occlusive components.
— The structures of consonant groups (STR, SPR and MPL only were considered) are badly deteriorated in any case deterioration of the group is much greater than the sum of deteriorations of phonemes considered in isolation
— As a final consideration we might say that broadly speaking, most affected are those phoneme structures that carry the greatest *quantity of information (consonants, particularly occlusives)*

CONCLUSIONS

Comprehension of messages in environments containing road traffic noise will be considerably deteriorated with respect to individual phonemes and isolated words with low resonance whereas comprehension of long segments (sentences and groups of sentences) is satisfactory Furthermore comprehension increases with message redundancy

URBAN TRAFFIC NOISE, CARDIOCIRCULATORY ACTIVITY AND CORONARY RISK FACTORS

L. Verdun d Cantogno, R. Dallerba, P.S. Teagno, L. Cocola

From the Department of Audiology and the 1st Department of Medical Patology University of Turin, Turin, Italy

SCOPE OF THE RESEARCH

The aim of this research was an assessment of the effect of road noise lasting 10 on cardiocirculatory activity and various blood chemistry indices, particulary those apparently associated with the pathogenesis of arteriosclerosis. Normal, dysmetabolic and coronaropathic subjects were examined

While it can readily be appreciated that certain stimuli can act on the cardiovascular apparatus, leading to changes in the work of the heart and its performances, it is less easy to understand how certain psychological and emotional conditions, or certain sensorial stimuli completely mediated by the CNS, influence the heart and its vessels, thus supporting atheroma, endoarterial thromboses or serious arrhytmias.

Acoustic stimuli offer an ideal method for the study of effects mediated by the CNS, since they can be exactly reproduced and measured in the absence of every other factor likely to influence cardiac frequency and arterial pressure, or left ventricular performance as assessed by simultaneous ECG phonocardiographic and carotid pulse recordings. Attention was also given to the blood chemistry indices known as related to coronary risk factors. Direct evaluation of catecholamine levels was not attempted, because this technique gives widely scattered results, even under normal conditions. Urinary catecholamines excreted during the test were however taken into consideration. The limitations of this method are well known.

MATERIAL AND METHODS

The absence of literature data concerning the effect of traffic noise on the parameters chosen for study suggested the advisability of preceding the experiment by a series of investigations of the effect of white noise and speech noise (100 dB and 80 dB intensity continuous stimulation for 10′ or for 1 followed by an interrupted stimulation for 9′) in 16 subjects, to determine the effect of noise of different spectrum and intensity administered with different modalities. This preliminary study (details in the press) showed statistically significant differences between stimulated and control subjects. We therefore began by exposing 33 subjects aged 20-70 yr to road noise. A further 11 normal subjects (mean age 27 yr) were studied for comparison, i.e. they were subjected to all the experimental procedures in the absence of road noise (control group).

Prior audiometric examination showed that all subjects had normal hearing for age. Only male subjects were examined, so as to ensure that responses were not affected by neurohormonal and neurophsychic factors pertinent to the two sexes.

The patients were divided into 3 groups (11 normals, average age 36.7 yr 11 diabetic or dyslipaemic, average age 46 4 yr 11 coronaropathic, average age 52 yr). As already stated, the average age of the 11 controls was 27 yr A division was also drawn between subjects aged more and less than 45 yr., i.e. 17 (mean

57.3 yr) and 16 (mean 32.7 yr) respectively excluding the controls.

Fifteen minutes after being settled on a bed in an Amplifon standard G5 silent booth erected in a room lined with soundproof panels, each subject was exposed to a tape consisting of 10 one minute recording of traffic noise registered at 10 different points in Turin Its characteristics were

L_m dB	L_{eq} dB	$\sigma +$ dB
88 8	89 4	2.35
L_m dB (A)	L_{eq} dB (A)	$\sigma +$ dB (A)
71 6	73 1	3 54

This noise was fed through a Uher 4400 Stereo Report I C recorder to the circuit of an Amplaid 500 Audiometer calibrated in dB SPL, and then to the subject s headphones. It was used at its true intensity which was checked with a Brüel & Kjaer phonometer fitted with a model 1613 octave filter

Neither the normal nor the control subjects displayed basal changes in blood chemistry para meters in blood pressure or in electrocardiographic and phonocardiographic patterns. Each patient had been fasting for at least 6 hr Five blood samples were taken as follows 20 and immediately before stimulation — the arithmetical mean of these values was used as the "basal value — 10 when the tape stopped and 30 and 90 after it started To avoid problems of stress related to the blood samples a butterfly needle was used kept patent with saline

There was no significant difference between the two basal values, bearing in mind the scatter displayed by these data under physiological conditions Sugar insulin uric acid, total lipids, cholesterol and triglycerides were measured in each sample using the following methods

— Blood Sugar Enzymatic determination with G6-PD-hexochinase (Biochemica test combination kit)

— Blood Insulin Richter radioimmunological kit utilizing a Packard " Tricarb Liquid Scintillation Spectrometer

— Blood Uric Acid "Urica Quant" colorimetric enzymatic method (Biochemica Test Combination)

— Total Lipids Colorimetric method of Zoellner & Kirch

— Cholesterol Biochemica Test Combination Kit according to D Watson B Zak and H H Lefler

— Triglycerides Enzymatic determination of serum concentration with Biochemica Test Combination Kit

— Urinary Catecholamines were determined fluorimetrically immediately before and immediately after the examination so that their excretion during the test could be known by their concentration in the samples.

Blood pressure was measured before during and after the stimulation with road noise 0-1 2 3-4 5-6 7 8 9 10 11 12 13 20 30-60 90 with an Erka " Diasist apparatus, using a pneumatic cuff fitted with a microphone for the registration of Korotkoff tones. Systolic and diastolic pressure values were automatically indicated every minutes on dials with a margin of error of less than 1 5 %.

ECG and polygraphic data were obtained with a 8-channel Elema Schönander Mingograf 81 " giving a simultaneous ECG 4-frequency phonocardiogram and carotid pulse recording Polygraphic records were taken at the same intervals as those used to record arterial pressure Examination of the ECG phonocardiogram and carotid pulse data gave and indication, inter alia of cardiac frequency The distance in terms of time and the relation between certain features of the heart cycle shown by these recording were than calculated so that the influence of the traffic noise on the heart performance could be detected and studied

The following systolic times and indices were considered

— LVET (left ventricular ejection time) from the foot of the ascending branch of the carotid sphygmogram to its dicrotic incisure)

— $S_1 S_2$ (mechanical systole) from the 1st component of the first sound to the aortic component of the 2nd sound

— PEP (pre-ejection period or tension time or pre-expulsion systole) from the start of the Q wave to the foot of the ascending branch of the carotidogram, less the PTT

— PTT (pulse transmission time) from the

aortic component of the 2nd sound to the dicrotic incisure of the carotid pulse.

— Q S_1 (Total or electomechanical systole) from the start of the Q wave to the first component of the 1st sound.

— Q_1-S_1 (deformation time) from the start of the Q wave to the first component of the first sound.

— ICT (isovolumetric contraction time) from the first component of the 1st sound to the foot of the ascending branch of the carotid sphygmogram, less the PTT

— PEP/LVET expresses left ventricular performance, LVET/ICT seems more closely related to myocardial contractility

The arithmetical mean of 10 beats was calculated for each systolic time corrected for frequency and compared with the normal theoretical values, to obtain significant data on myocardial performance. In addition, the product of cardiac frequency with systolic arterial pressure offers a good indication of coronary flow and myocardial oxygen needs.

RESULTS

The data were expressed as percents of the initials values referred as 100 and analyzed by applying Student's interval estimation with $P = 0.05$. The controls were compared with each of the three groups and with the stimulated series as a whole. Comparison was also made between subjects aged less and more than 45 yr.

After illustrating the pattern displayed by each parameter separately, an account will be given of their behaviour in normal, dysmetabolic and coronaropathic subjects.

BLOOD CHEMISTRY PARAMETERS

Sugar

Road noise brought about an immediate increase in blood sugar. This was more evident (over 50 % of cases) in coronary and dysmetabolic patients (Fig. 1). At 30' values were still high in 50 % of the normal subjects probably because they were younger. Values, in fact, differed significantly in function of age at 30' and 90' (Fig. 2).

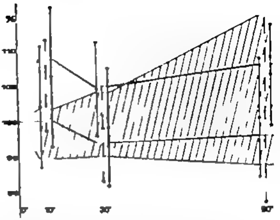

Fig. 1. Blood sugar. Normal subjects •——• Dysmetabolic subjects ★—— ——★ Coronary patients ○——○. Range of variation in unstimulated subjects ////////. Range of variation in stimulated subjects ═══.

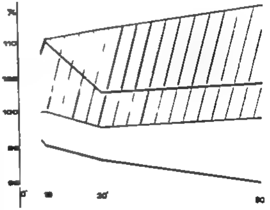

Fig. 2. Blood sugar. Subjects aged between 20 and 45 yr ////////. Subjects aged between 46 and 70 yr ═══.

Insulin.

Traffic noise was accompanied by a marked increase in band width in both normal and dysmetabolic subjects. This was more evident at 90' especially in the normal cases (Fig. 3). At the end of the test, levels were well up in about 80 % of normal and 50 % of dysmetabolic subjects, whereas they were down in 50 % of the coronary group. This, once again, may be attributed to age, since a marked, late rise in blood insulin is typical in younger subjects (Fig. 4).

57 3 yr) and 16 (mean 32.7 yr) respectively excluding the controls.

Fifteen minutes after being settled on a bed in an Amplifon standard G5 silent booth erected *in a room lined with soundproof panels*, each subject was exposed to a tape consisting of 10 one-minute recording of traffic noise registered at 10 different points in Turin Its characteristics were

L_m dB	L_{eq} dB	$\sigma \pm$ dB
88 8	89 4	2.35
L_m dB (A)	L_{eq} dB (A)	$\sigma \pm$ dB (A)
71 6	73 1	3 54

This noise was fed through a Uher 4400 Stereo Report I C recorder to the circuit of an Amplaid 500 Audiometer calibrated in dB SPL, *and then to the subject's headphones*. It was used at its true intensity which was checked with a Brüel & Kjaer phonometer fitted with a *model 1613* octave filter

Neither the normal nor the control subjects displayed basal changes in blood chemistry para meters in blood pressure or in electrocardiographic and phonocardiographic patterns Each patient had been fasting for at least 6 hr Five blood samples were taken as follows 20 and immediately before stimulation — the arithmetical mean of these values was used as the "basal value" — 10 when the tape stopped, and 30 and 90 after it started To avoid problems of stress related to the blood samples a butterfly needle was used kept patent with saline

There was no significant difference between the two basal values, bearing in mind the scatter displayed by these data under physiological conditions Sugar insulin uric acid total lipids, cholesterol and triglycerides were measured in each sample, using the following methods

— *Blood Sugar Enzymatic determination with* G6-PD-hexochinase (Biochemica test combination kit)

— *Blood Insulin Richter radioimmunological* kit, utilizing a "Packard" Tricarb Liquid Scintillation Spectrometer

— Blood Uric Acid "Urica Quant" colorimetric enzymatic method (Biochemica Test Combination)

— Total Lipids Colorimetric method of Zoellner & Kirch

— Cholesterol Biochemica Test Combination Kit according to D Watson, B Zak and H H Lefler

— Triglycerides Enzymatic determination of serum concentration with Biochemica Test Combination Kit

— Urinary Catecholamines were determined *fluorimetrically immediately* before and immediately after the examination so that their excretion during the test could be known by *their concentration in the samples*.

Blood pressure was measured before, during and after the stimulation with road noise 0-1 2 3-4 5-6 7-8 9 10 11 12 13 20 30-60 90' with an Erka Diasist apparatus, using a pneumatic cuff fitted with a microphone for the registration of Korotkoff tones. Systolic and diastolic pressure values were automatically indicated every minutes on dials with a margin of error of less than 1 5 %.

ECG and polygraphic data were obtained with a 8-channel Elema Schönander "Mingograf 81" giving a simultaneous ECG 4-frequency phonocardiogram and carotid pulse re *cording. Polygraphic records* were taken at the same intervals as those used to record arterial pressure Examination of the ECG phonocar *diogram and carotid pulse data gave and indi*cation, *inter alia of cardiac frequency The* distance, in terms of time, and the relation between certain features of the heart cycle shown by these recording were than calculated, so that the influence of the traffic noise on the heart performance could be detected and studied

— LVET (left ventricular ejection time) from the foot of the ascending branch of the carotid sphygmogram to its dicrotic incisure)

— S_1 S_2 (mechanical systole) from the 1st component of the first sound to the aortic component of the 2nd sound

— PEP (pre-ejection period or tension-time or pre-expulsion systole) from the start of the Q wave to the foot of the ascending branch of the carotidogram less the PTT

— PTT (pulse transmission time) from the

aortic component of the 2nd sound to the dicrotic incisure of the carotid pulse.

— Q_1-S_2 (Total or electomechanical systole) from the start of the Q wave to the first component of the 1st sound.

— Q_1-S_1 (deformation time) from the start of the Q wave to the first component of the first sound.

— ICT (isovolumetric contraction time) from the first component of the 1st sound to the foot of the ascending branch of the carotid sphygmogram, less the PTT

— PEP/LVET expresses left ventricular performance, LVET/ICT seems more closely related to myocardial contractility

The arithmetical mean of 10 beats was calculated for each systolic time corrected for frequency and compared with the normal theoretical values, to obtain significant data on myocardial performance. In addition, the product of cardiac frequency with systolic arterial pressure offers a good indication of coronary flow and myocardial oxygen needs.

RESULTS

The data were expressed as percents of the initials values referred as 100, and analyzed by applying Student's interval estimation, with P = 0.05. The controls were compared with each of the three groups and with the stimulated series as a whole. Comparison was also made between sujects aged less and more than 45 yr

After illustrating the pattern displayed by each parameter separately an account will be given of their behaviour in normal, dysmetabolic and coronaropathic subjects.

BLOOD CHEMISTRY PARAMETERS

Sugar

Road noise brought about an immediate increase in blood sugar This was more evident (over 50 / of cases) in coronary and dysmetabolic patients (Fig. 1). At 30' values were still high in 50 of the normal subjects probably because they were younger Values, in fact, differed significantly in function of age at 30' and 90' (Fig. 2).

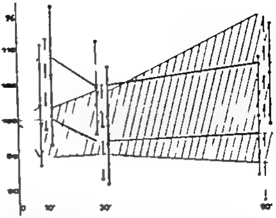

Fig 1 Blood sugar Normal subjects •———• Dysmetabolic subjects ★—— ——★ Coronary patients O———O Range of variation in unstimulated subjects ////////// Range of variation in stimulated subjects ═══

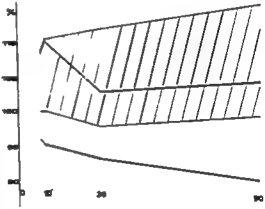

Fig 2 Blood sugar Subjects aged between 20 and 45 yr ////////// Subjects aged between 46 and 70 yr ═══

Insulin.

Traffic noise was accompanied by a marked increase in band width in both normal and dysmetabolic subjects. This was more evident at 90' especially in the normal cases (Fig. 3). At the end of the test, levels were well up in about 80 / of normal and 50 / of dysmetabolic subjects, whereas they were down in 50 / of the coronary group. This, once again, may be attributed to age, since a marked, late rise in blood insulin is typical in younger subjects (Fig. 4).

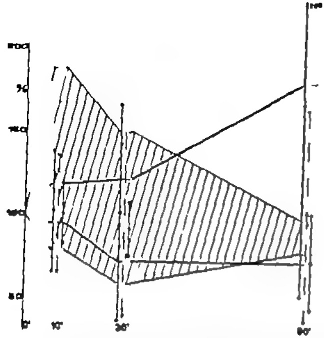

Fig 3 Serum insulin. Normal subjects ——— Dysmetabolic subjects ★—— • ——★ Coronary patients O———O Range of variation in unstimulated subjects ////////// Range of variation in stimulated subjects

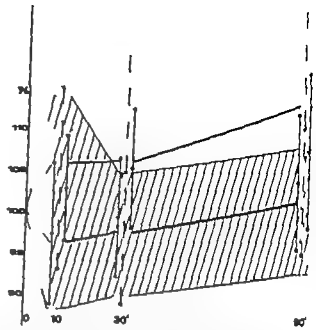

Fig 5 Total lipids. Normal subjects •——• Dysmetabolic subjects ★—— • ——★ Coronary patients O———O Range of variation in unstimulated subjects ////////// Range of variation in stimulated subjects

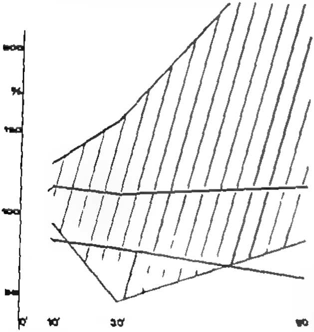

Fig 4 Serum insulin. Subjects aged between 20 and 45 yr ////////// Subjects aged between 46 and 70 yr

Total lipids

At 30 and 90 both coronary and dysmetabolic subjects displayed an increase in blood lipids. Band values expanded to a much greater degree in the dysmetabolic than in the other groups (Fig 5) In the normal subjects values were comparable with these observed in the controls. No significant differences in function of age could be made out

Triglycerides

Road noise caused a fall in values that appeared earlier (10 and 30') in the dysmetabolic as opposed to the coronary subjects. At 90 there was an increase of band amplitude in the normal group (Fig. 6) The fall at 30 was more marked in patients over 45 yr (Fig 7)

Blood cholesterol

Values increased after 30 and 90 in about 50 of the normal subjects. Increased band amplitude was noted from the start especially in the coronary patients (Fig. 8) There was no significant difference in function of age

Uric acid

A marked increase was observed at 30 and 90 especially in the dysmetabolic group (Fig 9) Band amplitude also increased at an early stage in the coronary subjects, and later in the normal group Up to 30 increases were higher in the younger subjects (Fig. 10).

Total lipids

At 30 and 90 both coronary and dysmetabolic subjects displayed an increase in blood lipids. Band values expanded to a much greater degree in the dysmetabolic than in the other groups (Fig. 5) In the normal subjects values were comparable with these observed in the controls No significant differences in function of age could be made out.

Triglycerides

Road noise caused a fall in values that appeared earlier (10 and 30') in the dysmetabolic as opposed to the coronary subjects. At 90 there was an increase of band amplitude in the normal group (Fig. 6) The fall at 30 was more marked in patients over 45 yr (Fig. 7)

Blood cholesterol

Values increased after 30 and 90' in about 50 of the normal subjects. Increased band amplitude was noted from the start especially in the coronary patients (Fig. 8) There was no significant difference in function of age

Uric acid

A marked increase was observed at 30 and 90 especially in the dysmetabolic group (Fig 9) Band amplitude also increased at an early stage in the coronary subjects, and later in the normal group. Up to 30 increases were higher in the younger subjects (Fig 10)

Catecholamines

Values observed before and after the test are shown in Table 1 To obtain more accurate data it would have been necessary to keep the subjects completely at rest for 24 hr before and after the test. This, however was not possible In spite of their limitation the data showed that road noise enhanced catecholamine excretion in the dysmetabolic group The relatively slight entity of the stimulus and its nature lead one to suppose that nothing less than direct haematochemical determination of the catecholamine content would have given an accurate picture of this parameter The techniques required however are difficult to apply in vivo since very low quantities are involved Furthermore catecholamines are very rapidly inactivated in the body

ECG AND HEART PERFORMANCE

Road noise did not lead to any significant ECG changes, even in subjects with marked basal signs of chronic or sub-chronic myocardial ischemia During the course of the experiment isolated atrial or ventricular extrasystole were observed in some subjects, though these appeared to be devoid of particular significance

Left ventricular performance was indirectly assessed polygraphically by simultaneous ECG phonocardiographic and carotid pulse recording Comparison was made between the length of the PEP and LVET and of the relative importance on the ICT with respect to the initial DT The reciprocal relation between these parameters are indirect pointers to heart performance, especially as far as possible ischemia of the cardiac fibers is concerned Our results did not reveal any marked variations in these and in other parameters. The noise used was apparently insufficient to influence these indices to an appreciable extent

Changes in cardiac frequency were considered separately and together with systolic arterial pressure As already stated frequency times systolic pressure is regarded as one of the best pointers of coronary flow tension time index and myocardial oxygen consumption Traffic noise was responsible for a distinct increase of this index in the normal subjects, followed by a fall in response during the application of the stress (Fig. 11 A) A somewhat similar pattern was noted in the dysmetabolic group, though here values remained significantly high in 50 of cases until the end of the noise, after which there was a certain widening of the band (Fig. 11 B) In the coronary patients the increase was significant for a longer period in a larger number of cases (Fig 11 C)

CONCLUSIONS

Exposure to road noise in the form employed in our experiment was followed by enhancement or depression of several blood chemistry parameters, or a wider scattering of their values, as shown by an increase of band amplitude around a more or less unchanged mean On many occasions both responses were present though their relative importance varied Blood sugar displayed the earliest changes by contrast with the late response observed in the case of blood insulin

We were particulary struck by the extent of the blood uric acid response showing that noise has an effect on the metabolism of nucleic acids. As was to be expected normal subjects generally presented less significant changes, especially in total lipids and triglycerides. An immediate increase in blood sugar was noted only in 50 of this group as opposed to 80 of the others.

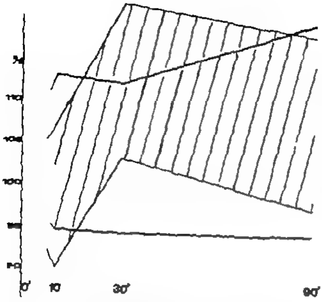

Fig 10 Blood uric acid. Subjects aged between 20 and 45 yr. Subjects aged between 46 and 70 yr

Catecholamines

Values observed before and after the test are shown in Table I To obtain more accurate data it would have been necessary to keep the subjects completely at rest for 24 hr before and after the test This, however was not possible In spite of their limitation the data showed that road noise enhanced catecholamine excretion in the dysmetabolic group The relatively slight entity of the stimulus and its nature lead one to suppose that nothing less than direct haematochemical determination of the catecholamine content would have given an accurate picture of this parameter The techniques required however are difficult to apply in vivo since very low quantities are involved Furthermore catecholamines are very rapidly inactivated in the body

ECG AND HEART PERFORMANCE

Road noise did not lead to any significant ECG changes, even in subjects with marked basal signs of chronic or sub-chronic myocardial ischemia. During the course of the experiment isolated atrial or ventricular extrasystole were observed in some subjects, though these appeared to be devoid of particular significance

Left ventricular performance was indirectly assessed polygraphically by simultaneous ECG phonocardiographic and carotid pulse recording. Comparison was made between the length of the PEP and LVET and of the relative importance on the ICT with respect to the initial DT The reciprocal relation between these parameters are indirect pointers to heart performance especially as far as possible ischemia of the cardiac fibers is concerned Our results did not reveal any marked variations in these and in other parameters. The noise used was apparently insufficient to influence these indices to an appreciable extent

Changes in cardiac frequency were considered separately and together with systolic arterial pressure As already stated frequency times systolic pressure is regarded as one of the best pointers of coronary flow tension time index and myocardial oxygen consumption Traffic noise was responsible for a distinct increase of this index in the normal subjects, followed by a fall in response during the application of the stress (Fig. 11 A) A somewhat similar pattern was noted in the dysmetabolic group, though here values remained significantly high in 90 % of cases until the end of the noise, after which there was a certain widening of the band (Fig 11 B) In the coronary patients the increase was significant for a longer period in a larger number of cases (Fig. 11 C)

CONCLUSIONS

Exposure to road noise in the form employed in our experiment was followed by enhancement or depression of several blood chemistry parameters, or a wider scattering of their values, as shown by an increase of band amplitude around a more or less unchanged mean. On many occasions both responses were present, though their relative importance varied Blood sugar displayed the earliest changes by contrast with the late response observed in the case of blood insulin

We were particulary struck by the extent of the blood uric acid response showing that noise has an effect on the metabolism of nucleic acids As was to be expected normal subjects generally presented less significant changes, especially in total lipids and triglycerides An immediate increase in blood sugar was noted only in 50 % of this group as opposed to 80 of the others,

the late insulin response was more and frequent. This was the only group y a late increase in cholesterol values, changes in uricemia included both, and increases, leading to an over 100 / ent in band amplitude at 90

ic and dyslipaemic subjects presented significant changes in total lipids, des and uric acid. This group displayed t evident and erliest (10' and 30') fall cerides, by contrast with the increase lipids and their wider band amplitude nd 90'

ary patients showed a similar pattern, apart from blood suger their changes s striking. In this group the main fea- re variations in band amplitude, except ase of total lipids, whereas triglycerides shifted less than in the dysmetabolic but earlier than in the normal group. roduct of cardiac frequency and systolic arterial pressure — an index of change in coronary flow and the metabolic requirements of the myocardium — increased to a greater extent and for longer after the cessation of the road noise in the coronary patients as was to be expected on theoretical grounds. This index tended to fall during the stimulation period in the normal subjects, whereas it stayed high throughout this period in the dysmetabolic group. This behaviour shows that exposure to traffic noise may be responsible for an increase in myocardial energy requirements by influencing frequency and systolic pressure.

Our blood chemistry data are to scanty to permit full interpretation of the changes observed. It can, however be stated that road noise of the type employed can lead to distinct changes in all the parameters taken into consideration these being of great importance as coronary risk factors in general terms, and as tending to support atheroma.

URBAN TRAFFIC NOISE AUDITORY AND EXTRA AUDITORY EFFECTS

Concluding remarks

G Rossi

From the Department of Audiology University of Turin Turin Italy

In this series of papers we have given particular attention to the effects of traffic noise on features of the auditory function verbo-acoustic communication, some phenomena associated with the activity of the central nervous system and the cardiocirculatory apparatus.

The question of the effects of road noise has been examined for the first time in such a way as to allow albeit through no more than partial findings, an overall view of a situation that faces each of us day by day Some very interesting data have emerged and further research is under way to examine them more closer This was also be extended to cover other questions, such as the secretion of certain hormones, a subject that appears to have been overlooked so far

The question examined in these papers is of importance and its evaluation involves the assessment of traffic noise as a factor in modern life, and of the as yet unestablished consequences that it may have under certain conditions, on the physiological dwindling of sensory performance in function of age as well as the onset of various morbid signs that are by no means the prerogative of senescence

Our results must of course, be read in the light of the spectral composition of the noise and in the light of the methodological approach employed in the experiments. Any form of generalization would be out of place With this warning against the drawing of general or absolute conclusions in mind however it seems safe to hazard the suggestion that the noise produced by road traffic is not without its effects on various functions and activities performed by man This is of particular significance to those who work in noisy surroundings and what is more fail to find outside such surroundings the conditions that would enable them to recover their lost physical and psychological energies

In the light of our at present fragmentary knowledge, the enunciation of a detailed programme for the solution of this question would be both illogical and premature Yet one would, perhaps, be not too far of the mark with respect to the real terms in which the question of pollution in the form of traffic noise presents itself if one were to postulate its solution through combined efforts in the field of mechanical engineering and urbanistic technique and regulation designed to reduce the production of noise as far as possible and on the other hand to discipline traffic in such a way as to take into account the data and models provided by phonometry and their elaboration Initiatives of this kind must of course be flanked by carefully thought out and severely applied laws, coupled with the due instruction and sensitization of public opinion through advertising

No effort must be left unspared, since that a reduction, however slight, in the present intensity of the noise produced by road traffic would help to diminish the harmful effects it causes in man, one reason for which is its characteristic continuity

Introduction

The correlation of hearing disability and hypothyroidism has been made by many observers. Kemp (1907) was the first to describe a case of acquired hypothyroidism with associated deafness. Similar descriptions reporting cases with acquired hypothyroidism and associated deafness appeared later (King, 1907; Moehlig, 1927). A conductive hearing loss was reported and the cause was attributed to a myxedematous middle ear (McMahon, 1947). Recently, utilizing more precise hearing tests, most of the hearing loss was shown to be of a sensorineural type, sometimes with an additional component of the middle ear forming a mixed type of hearing loss (Howarth & Lloyd, 1956; Hilger, 1956; Ritter & Lawrence, 1960; De Vos, 1963). Hearing disability seems to appear only in a certain percentage of the patients with proven hypothyroidism. Post (1964) reported forty-two patients with proven hypothyroidism of which a sensorineural hearing loss was demonstrated in only four patients. Heinemann (1968) claimed that only six patients out of a group of forty-two patients with various hypothyroid conditions had a sensorineural hearing loss. On the whole it appears that in acquired hypothyroidism the hearing disability appears in a far smaller percentage of patients than it does in congenital hypothyroidism.

The severity of the hearing impairment in acquired hypothyroidism does not seem to be as severe as in the congenital state (Ritter & Lawrence, 1960). Hearing impairment in acquired hypothyroidism is not explained by organic damage to the labyrinth. The inability to demonstrate a definite morphological correlation with the hearing impairment may be due to limitations of the histological method. De Vos (1963) reported that the organ of Corti was not found to be morphologically changed in animals in a state of acquired hypothyroidism. The only anatomical lesion found was a slight degeneration of the spiral ganglion. Experiments on animals with induced hypothyroidism showed no change in the sensory cells (Ritter, 1967). Kohonen et al. (1971) found minute morphological changes but considered them insufficient to explain the functional impairment. The lack of findings of lesions in the neural structures of the cochlea and yet the slight degeneration of the spiral ganglion noted by De Vos (1963), together with the information of a perceptive deafness in a certain percentage of the humans with hypothyroidism, brought De Vos to presume a nervous or a central involvement of the auditory system. Conversely, a precipitate of acid mucopolysaccharides was demonstrated in the scalae of cochleas from hypothyroid guinea pigs in recent histochemical observations (Shatzle & Haubrich, 1967). As most researchers did not find structural or morphological lesions that could explain the hearing loss we thought that the subject would be elucidated by studying the difference in the function of the peripheral hearing mechanism in hypothyroidism. In this study we chose to compare cochlear action potentials aroused by unfiltered clicks before and after induced hypothyroidism.

Introduction

The correlation of hearing disability and hypothyroidism has been made by many observers. Kemp (1907) was the first to describe a case of acquired hypothyroidism with associated deafness. Similar descriptions reporting cases with acquired hypothyroidism and associated deafness appeared later (King, 1907 Moehlig, 1927). A conductive hearing loss was reported and the cause was attributed to a myxedematous middle ear (McMahon, 1947). Recently utilizing more precise hearing tests most of the hearing loss was shown to be of a sensorineural type, sometimes with an additional component of the middle ear forming a mixed type of hearing loss (Howarth & Lloyd 1956 Hilger 1956 Ritter & Lawrence 1960 De Vos 1963). Hearing disability seems to appear only in a certain percentage of the patients with proven hypothyroidism. Post (1964) reported forty-two patients with proven hypothyroidism of which a sensorineural hearing loss was demonstrated in only four patients. Heinemann (1968) claimed that only six patients out of a group of forty-two patients with various hypothyroid conditions had a sensorineural hearing loss. On the whole it appears that in acquired hypothyroidism the hearing disability appears in a far smaller percentage of patients than it does in congenital hypothyroidism.

The severity of the hearing impairment in acquired hypothyroidism does not seem to be as severe as in the congenital state (Ritter & Lawrence 1960). Hearing impairment in acquired hypothyroidism is not explained by organic damage to the labyrinth. The inability to demonstrate a definite morphological correlation with the hearing impairment may be due to limitations of the histological method. De Vos (1963) reported that the organ of Corti was not found to be morphologically changed in animals in a state of acquired hypothyroidism. The only anatomical lesion found was a slight degeneration of the spiral ganglion. Experiments on animals with induced hypothyroidism showed no change in the sensory cells (Ritter 1967). Kohonen et al. (1971) found minute morphological changes but considered them insufficient to explain the functional impairment. The lack of findings of lesions in the neural structures of the cochlea and yet the slight degeneration of the spiral ganglion noted by De Vos (1963) together with the information of a perceptive deafness in a certain percentage of the humans with hypothyroidism brought De Vos to presume a nervous or a central involvement of the auditory system. Conversely a precipitate of acid mucopolysaccharides was demonstrated in the scalae of cochleas from hypothyroid guinea pigs in recent histochemical observations (Shatzle & Haubrich, 1967). As most researchers did not find structural or morphological lesions that could explain the hearing loss we thought that the subject would be elucidated by studying the difference in the function of the peripheral hearing mechanism in hypothyroidism. In this study we chose to compare cochlear action potentials aroused by unfiltered clicks before and after induced hypothyroidism.

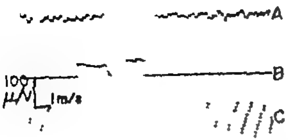

Fig. 2 Original recording. Acoustic evoked potentials by unfiltered clicks at 80 dB SPL. A = direct recording, B = average of 50 presentations. C = time scale.

(*b*) Unfiltered clicks from a home-made alternating positive–negative pulse generator

(*c*) Filtered clicks obtained by passing unfiltered clicks through a narrow-band filter tuned to the desired central frequency (Madsen 20 1/3 octave filter set)

The intensity required was controlled by a home-made power amplifier and monitored by a permanently installed condensor microphone (Brüel & Kjaer type 4132) connected to a frequency analyzer that was used as a linear sound level meter (Brüel & Kjaer type 2105). The potentials from the animal were passed through a pre-amplifier and then amplified (Medelec AVM 6). The signal was then displayed and recorded by an ultraviolet beam (Medelec DFO 6 + T II). The unfiltered clicks form a square wave with a width of 0.1 msec at a rate of 10 pulses per second. The pulses are of alternating polarity.

In Fig. 2 is shown an example of the recording obtained with the instrumentation used in this study. The upper tracing is the direct recording from the electrode placed in the empty facial canal in the vicinity of the VIII nerve. The middle tracing shows the averaging of 50 presentations of unfiltered clicks at 80 dB sound pressure level. The number of presentations and the length of the recording which had to be averaged can be varied at will according to the needs and recording conditions. The lower tracing is the time scale. It can be moved so as to be superimposed on the upper or middle tracings, thus allowing a very accurate measurement of time-related phenomena.

Procedures

Complex problems arise in this sort of experiment where electrical measurements made over a few months are to be compared. The problem had to be resolved of implanting an electrode and keeping it in position without causing a tissue reaction that would alter the recording conditions, and furthermore to be both near the VIII nerve in order to get clear recordings, yet be far enough from the inner and middle ear structures so as not to cause operative or postoperative damage. We developed a novel technique, described below, which seemed to solve these problems.

The superior bulla is exposed using sedation with 10–12 mg Nembutal and local anaesthesia with Procaine. After opening the bulla one can see in the posterior part the protrusion made by the vertical and horizontal semicircular canals and in the anterior part, the bluish colour of the thin bony wall separating the bulla from the cavity of the middle ear (Fig. 3). Inferiorly the incudo-malleolar bone is easily

Material

Stainless steel electrodes were chronically implanted into the ear of 40 guinea pigs weighing between 250–300 grams From this group 4 animals were discarded because the recorded action potentials were weak and unstable The fact is explained by damaging of the insulation of the electrode during implantation These animals were used as a normal control group for blood tests Two animals developed post operative ear infection and had to be eliminated An additional 4 animals were used to check the range of variability of the recorded VIII nerve action potentials. Measurements carried on over more than a month showed large variability in magnitude of the A P recorded from different animals but in the same animal the action potentials remained stable. In the remaining 30 guinea pigs used for further analysis hypothyroidism was induced. The animals were divided into three equal groups In the first group a state of hypothyroidism was induced by administering between 4–5 mCi per animal of radioiodine (I^{131}) intraperitoneally Control performed one month later failed to detect any remnant of radiation from the neck The second group underwent total thyroidectomy A state of hypothyroidism was provoked in the third group by a daily oral administration of 1–7 mg of propylthio-uracil

Instrumentation

The guinea pigs were put in a soundproof case inside a metal box with a mesh top (Fig. 1) The sound stimuli were delivered to the animal from a horn-type loudspeaker (Geloso horn loudspeaker) Three types of stimuli could be used

(a) Pure tones from a sine generator (Krohn Hite 5100 A function generator).

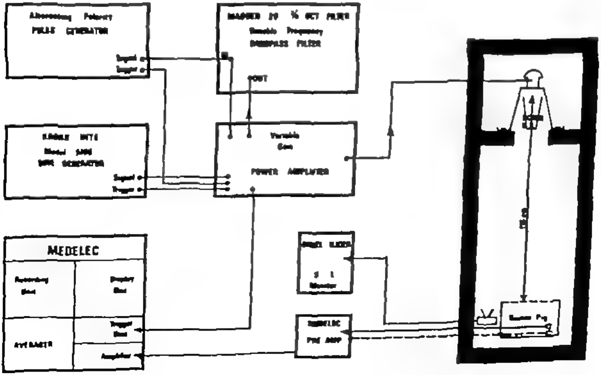

Fig 1 Set-up used for stimulation and recording of cochlear potentials.

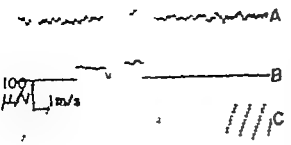

Fig. 2. Original recording. Acoustic evoked potentials by unfiltered clicks at 80 dB SPL. A = direct recording. B = average of 50 presentations. C = time scale.

(*b*) Unfiltered clicks from a home-made alternating positive–negative pulse generator.

(*c*) Filtered clicks obtained by passing unfiltered clicks through a narrow-band filter tuned to the desired central frequency (Madsen 20 1/3 octave filter set).

The intensity required was controlled by a home-made power amplifier and monitored by a permanently installed condensor microphone (Brüel & Kjaer type 4132) connected to a frequency analyzer that was used as a linear sound level meter (Brüel & Kjaer type 2105). The potentials from the animal were passed through a pre-amplifier and then amplified (Medelec AVM 6). The signal was then displayed and recorded by an ultraviolet beam (Medelec DPO 6 + T II). The unfiltered clicks form a square wave with a width of 0.1 msec, at a rate of 10 pulses per second. The pulses are of alternating polarity.

In Fig. 2 is shown an example of the recording obtained with the instrumentation used in this study. The upper tracing is the direct recording from the electrode placed in the empty facial canal in the vicinity of the VIII nerve. The middle tracing shows the averaging of 50 presentations of unfiltered clicks at 80 dB sound pressure level. The number of presentations and the length of the recording which had to be averaged can be varied at will according to the needs and recording conditions. The lower tracing is the time scale. It can be moved so as to be superimposed on the upper or middle tracings, thus allowing a very accurate measurement of time-related phenomena.

Procedures

Complex problems arise in this sort of experiment where electrical measurements made over a few months are to be compared. The problem had to be resolved of implanting an electrode and keeping it in position without causing a tissue reaction that would alter the recording conditions, and furthermore to be both near the VIII nerve in order to get clear recordings, yet be far enough from the inner and middle ear structures so as not to cause operative or postoperative damage. We developed a novel technique, described below, which seemed to solve these problems.

The superior bulla is exposed using sedation with 10–12 mg Nembutal and local anaesthesia with Procaine. After opening the bulla one can see in the posterior part the protrusion made by the vertical and horizontal semicircular canals and, in the anterior part, the blueish colour of the thin bony wall separating the bulla from the cavity of the middle ear (Fig. 3). Inferiorly, the incudo-malleolar bone is easily

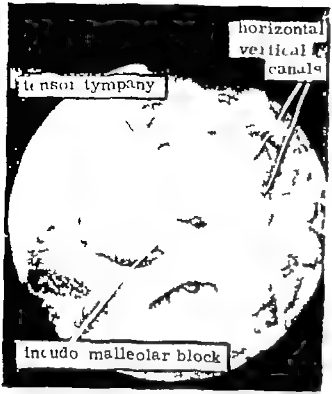

Fig 3 Exposure of superior bulla.

Fig 4 Opening of facial canal and section of the tendon of tensor tympanum muscle

recognized The ascending part of the facial canal passes through the denser bone between the semicircular canals and the bluish area

A small hole was drilled in the denser bone the nerve was exposed and cut (Fig 4) The tensor tympanum was visualized between the medial wall of the middle ear and the incudo-malleolar bone and severed (Fig 4) A specially made stainless steel electrode was introduced into the facial canal to a depth of 4.5 mm (Fig 5) The electrode was fixed in place with a drop of self-curing acryl The distal end of the electrode was brought through the skin in the occipital region and the wound was cleaned and sutured An inactive electrode made from uninsulated stainless steel was passed through the skin in the neck region

Immediately after the operation the action potentials aroused by unfiltered clicks of varying intensity were recorded Additional measurements were performed several days later If the recorded action potentials remained the same as after the operation the protruding part of the electrode was cut and the skin pinched in order to bury the electrode After approximately 2 months (considered sufficient to induce the hypothyroidism) the skin was

Fig 5 Positioning of the electrode in the facial canal

opened under local anaesthesia and light sedation with 6–8 mg Nembutal. The electrode was exposed and for several days new and repeated measurements were performed. No blood tests were performed during this period in order to confirm by laboratory findings the assumption that hypothyroidism was really achieved. In order to avoid artefacts connected with changes in the pulmonary ventilation due to anaesthesia, the sedation was the same during the various measurements and only just enough to keep the animal quiet. Several animals from each group were put on a replacement therapy of a daily oral administration of 1 mg of thyroidea sicca. The remaining animals were sacrificed and their blood analysed. At this time the middle ear was examined microscopically to make sure that no pathology had developed during the experimental period.

Results

Action potentials of 30 guinea pigs were compared with the potentials recorded before they became hypothyroid. All the guinea pigs showed changes following hypothyroidism in three main features: the magnitude, the shape and the delay time of the action potentials. Action potentials of a hypothyroid guinea pig that received radioiodine are illustrated in Fig. 6. Action potentials were recorded at varying acoustic intensities. A small change was seen in the shape and magnitude of the action potentials, especially at the lower intensities. At 8 weeks hypothyroidism was not yet fully induced. At 16 weeks there were marked changes in magnitude, shape and delay over the whole range of intensities.

The animal was put on replacement therapy for a period of 7 days to ascertain whether the changes in action potentials were *due to the* hypometabolic state. A swift recovery was obtained in the magnitude of the potentials, yet the shape of the potentials recorded *did not* match the original recordings. Blood tests performed 3 weeks after interruption of the replacement therapy showed PBI 0.7 μg % and T4 0.1. Action potentials measured before the animal was bled showed a disappearance of the improvement obtained during the replacement therapy.

Examples of action potentials obtained from 3 guinea pigs from the group that underwent total thyroidectomy are seen in Fig. 7. The action potentials aroused by a filtered click with a central frequency of 3.2 kHz at a S.P.L. of 80 dB are seen in the first column. Changes in the action potentials caused by hypothyroidism between 16 and 18 weeks are shown in the second column. The improvement obtained after 10 days of replacement therapy is demonstrated in the third column.

The changes during hypothyroidism caused by administration of propylthio-uracil for a period of 12 weeks on various acoustic stimuli are illustrated in Fig. 8. The changes in the action potentials aroused by unfiltered clicks and filtered clicks centered at 960 Hz, in one centered around 1.6 kHz, and one at 3.2 kHz, are shown. The intensity was 80 dB S.P.L. The delay time found in the recordings of the action potentials using the same intensity of sound stimuli during the hypometabolic state was increased by 0.3–0.6 *msec.*

Discussion

To extrapolate from the alteration of the action potentials in animal *experiments* to the hearing impairment observed in patients with hypothyroidism, is hazardous. The justification in doing so is that action potentials are the only signal *conveyed to the* brain and there

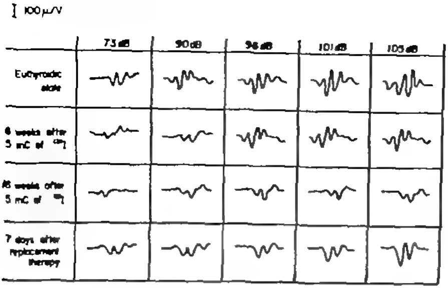

Fig 6 Graph obtained from the averaged responses of 50 presentations of unfiltered clicks In this animal the hypothyroidism was induces by 5 mCi of radioiodine The deterioration of the cochlear action potentials reached its maximum after 14–16 weeks and was more evident at lower intensity of sound stimuli.

fore they have to contain all the necessary information for the higher auditory centers to accurately process the acoustical message We conclude that a correlation exists between the diminished magnitude of the action potentials and the loss of hearing sensitivity found in hypothyroid patients This leads us to the suspicion that even hypothyroid patients having a normal threshold could have some disability in the supraliminal hearing which could be objectively demonstrated The change in the pattern of the signal could be related to some hearing disability in the hearing above the threshold

We believe that some hearing disability must exist above the threshold which is not detected by routine audiological methods The middle ear component as so frequently found accompanying the sensorineural hearing loss could have other explanations than the usual myxedematous changes in the middle ear An interference with normal propagation of sound waves through the cochlear scalae could have the same effect as in Menière s disease in which a mixed type of hearing loss is found without any middle ear pathology The observations made upon hypothyroid patients with a mixed hearing loss who unsuccessfully underwent regular treatment against a supposed pathology of the middle ear can be considered as proof Clinically it is well known that replacement therapy improves hearing but only

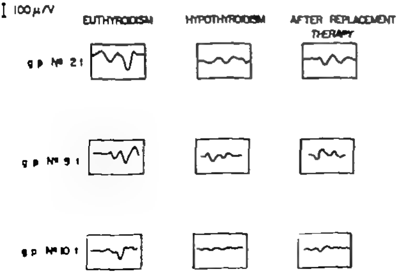

Fig 7 Hypothyroidism after surgical ablation of thyroid gland. A eraged action potentials evoked by 50 presentations of filtered clicks 1/3 octave and centered frequency 3 700 Hz at sound pressure level of 80 dB

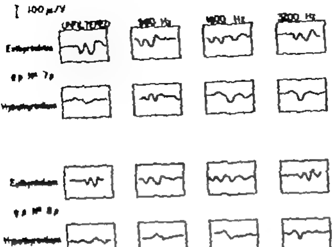

Fig. 8. Propylthio-uracil-induced hypothyroidism. Averaged action potentials evoked by 50 presentations of unfiltered clicks and 1/3 octave filtered clicks with different centered frequencies. Sound pressure level, 80 dB.

a few cases really reached the normal hearing level (Kohonen, Jauhiainen & Kaimio 1971).

In our study replacement therapy improved the magnitude of the action potentials, and in some cases it even reached the normal levels yet slight changes in the patterns of the action potentials remained. This leads us to the suspicion that even hypothyroid patients having a normal threshold could have some defect in the supraliminal hearing which could be objectively found by special auditory tests. The increased delay time of the action potentials found in our study could be correlated with the increased neural conduction time found in hypothyroid patients. A sluggish Achilles reflex is described in classical textbooks and recently an increased latency period in Auditory Evoked Response and unusual Békésy tracings due to hypothyroidism were found (Rubinstein, M. et al.).

Acquired hypothyroidism is believed to be far from uncommon, and aside from the clear-cut clinical cases many endocrinologists believe in the existence of sub-clinical forms. The results obtained in our study can easily be correlated with the clinical findings. Therefore it seems to us that more studies using this experimental model would be helpful. The information obtained could improve our knowledge concerning the specific pathology and contribute in establishing an early diagnosis in patients suffering from hypothyroidism.

Summary

Hypothyroidism was induced in guinea pigs by various methods. Using a new technique electrodes were permanently implanted and action potentials aroused by different sound stimuli recorded and measured. The results obtained before and during the hypometabolic state were analysed and compared with those obtained after replacement therapy. A tentative attempt was made to extrapolate the changes in pattern and magnitude of the action potentials caused by the experimentally induced hypothyroidism, to the hearing disorders observed in patients with thyroid deficiency.

Zusammenfassung

Hypothyroidism wurde im Meerschweinchen unter Verwendung verschiedener Methoden ausgelöst.

Eine neue Technik der ständigen Elektroden implantation ist gewählt worden wobei Aktionspotentiale verschiedener Geräusch stimuli gemessen und auf Tonband aufgenommen worden sind

Die Ergebnisse bevor und während hypometabolischer Zustände sind analysiert und mit denen nach einer Substitutionstherapie verglichen worden

Es wurde versucht die Änderungen in Muster und Grösse der Aktionspotentiale die durch den experimentell verursachten hypothyreotischen Zustand aufgetreten worden sind auf die verschiedene Hörstörungen welche hypothyreotische Patienten kennzeichnen zu extrapolieren

1 Einleitung

Der endemische Kretinismus im Zusammenhang mit Hör- und Sprachstörungen ist seit langem bekannt und hat immer wieder Diskussionen entfacht, inwieweit und ob überhaupt der Schilddrüse eine Bedeutung für die normale Entwicklung des Ohres zukommt. Ist es doch eine Tatsache, dass die Verbreitung der Gehörstörungen weder mit der Häufigkeit des endemischen Kretinismus noch mit der Intensität der Kropfendemie parallel geht (Trotter 1960, Greenwald 1960, Costa und Ferraris 1963). Erste Beschreibungen derartiger Krankheitsbilder gehen in frühe Zeitepochen zurück. So berichten römische Autoren über den Alpenkropf (Juvenal und Virtuv). Im 16. und 17. Jahrhundert weisen besonders Schweizer Ärzte wie Paracelsus und Felix Plater (1536–1614) auf den Kretinismus hin, wobei Plater als erster auf das Vorkommen von Taubstummheit „mit kropfiger und kretiner Degeneration" hinwies. In seinem 1656 in Basel erschienenen Buch „praxos medicae opus cum centuria posthuma emendatum et auct. a Felice Platero" erwähnt er eine Art von Taubheit, die in den Alpengegenden auftritt und durch Taubstummheit in Verbindung mit einem Kropf charakterisiert ist. Ätiologisch nimmt Plater an, dass die Erkrankung durch eine vom Kropf zum Ohr hin fliessende Flüssigkeit hervorgerufen wird. Er schreibt: *Sicuti in alpinis regionibus, hac de causa multos difficilem auditum ab ortu, vel mox in aetatis progressu una cum strumis illis ob similem causam familiaribus habere certimus* (nach Politzer 1907).

Eingehende Untersuchungen zu diesem Problemkreis blieben Forschern im vorigen Jahrhundert vorbehalten – allen voran H. Bircher (1883), dessen Ausführungen zur endemischen Taubstummheit grundlegende Aspekte eröffnete. Die Untersuchungen wandten sich jetzt mikromorphologischen Methoden zu, was durch den weiteren Ausbau [...] Othistologie mit ihrer verfeinerten Tech[...] wesentlich erleichtert wurde.
